ORGANIZATION AND CROP PRODUCTION PRACTICES ON GRAIN FARMS IN SELECTED AREAS OF THE NORTHERN GREAT PLAINS

By
R. S. Washburn
Assistant Agricultural Economist

Farm Management Reports - No. 2

Washington, D. C.
December 1939

STATEMENT OF COOPERATION AND ASSISTANCE

Thanks are extended to the many grain farmers through whose courtesies the securing of the field data was made possible.

For assistance in collecting the field data, the author wishes to thank the following:

Kenneth H. Myers of the Bureau of
Agricultural Economics;
William J. Edens, Morgan C.Rochester,
Henry M. Pevehouse, Cruz Venstrome,
Dale C. Kieffer, Fay A.Given,
Harry P. Hartkemeier, and
Nathan Koffsky,
Temporary employees of the Bureau of
Agricultural Economics.

CONTENTS

ORGANIZATION AND CROP PRODUCTION PRACTICES ON GRAIN FARMS IN SELECTED AREAS OF THE NORTHERN GREAT PLAINS

By R. S. Washburn, Assistant Agricultural Economist

INTRODUCTION

Successful farm planning necessitates a knowledge of the size and organization of farms and an estimate of the amount of time required to perform the field operations. Because of the need for such information, this study of farm organization and farm practice was made.

A survey of approximately 1240 farms in the major wheat producing areas of the Northern Great Plains, and of approximately 400 farms in the Pacific Northwest was concluded in June 1934. The farming areas surveyed in the Northern Great Plains are shown in figure 1. 1/ The number of farm records secured in each State and county, by type-of-farming areas, is shown in appendix table 25.

As the study aimed to show the methods of growing and handling crops, particularly wheat, the sample of farms may show a larger acreage of wheat and a higher proportion of the land in crops than would a county average. As no particular effort was made for any other selection, it is believed that the records obtained are typical of grain farms in the type-of-farming areas studied.

In certain sections of the Northern Great Plains, particularly in western North Dakota, eastern Montana, and in many areas of South Dakota, conditions of extreme drought prevailed in 1933, and very little harvest was reported in these drought areas. In these areas, therefore, the practices employed in a normal season, rather than those reported in 1933, are shown in this report.

The present report is the sixth in a series of Bureau of Agricultural Economics publications dealing with grain farms in the Northern Great Plains and in the Pacific Northwest. Previous publications are:

(1) Tillage, Planting and Harvesting Equipment on Grain Farms and Rates of Doing Field Work with these Implements when Drawn with Horse and with Tractor Power (Northern Great Plains and Pacific Northwest, 1933).

(2) Utilization of Tractors and Cost of Tractor Power on Grain Farms (Northern Great Plains and Pacific Northwest, 1933).

1/ Most of the areas surveyed lie within the boundaries of the region known as the Northern Great Plains Physiographic Province. Data were obtained from a few adjoining areas which, because of similarities in farm practice, have been considered in this report as a part of the Plains region.

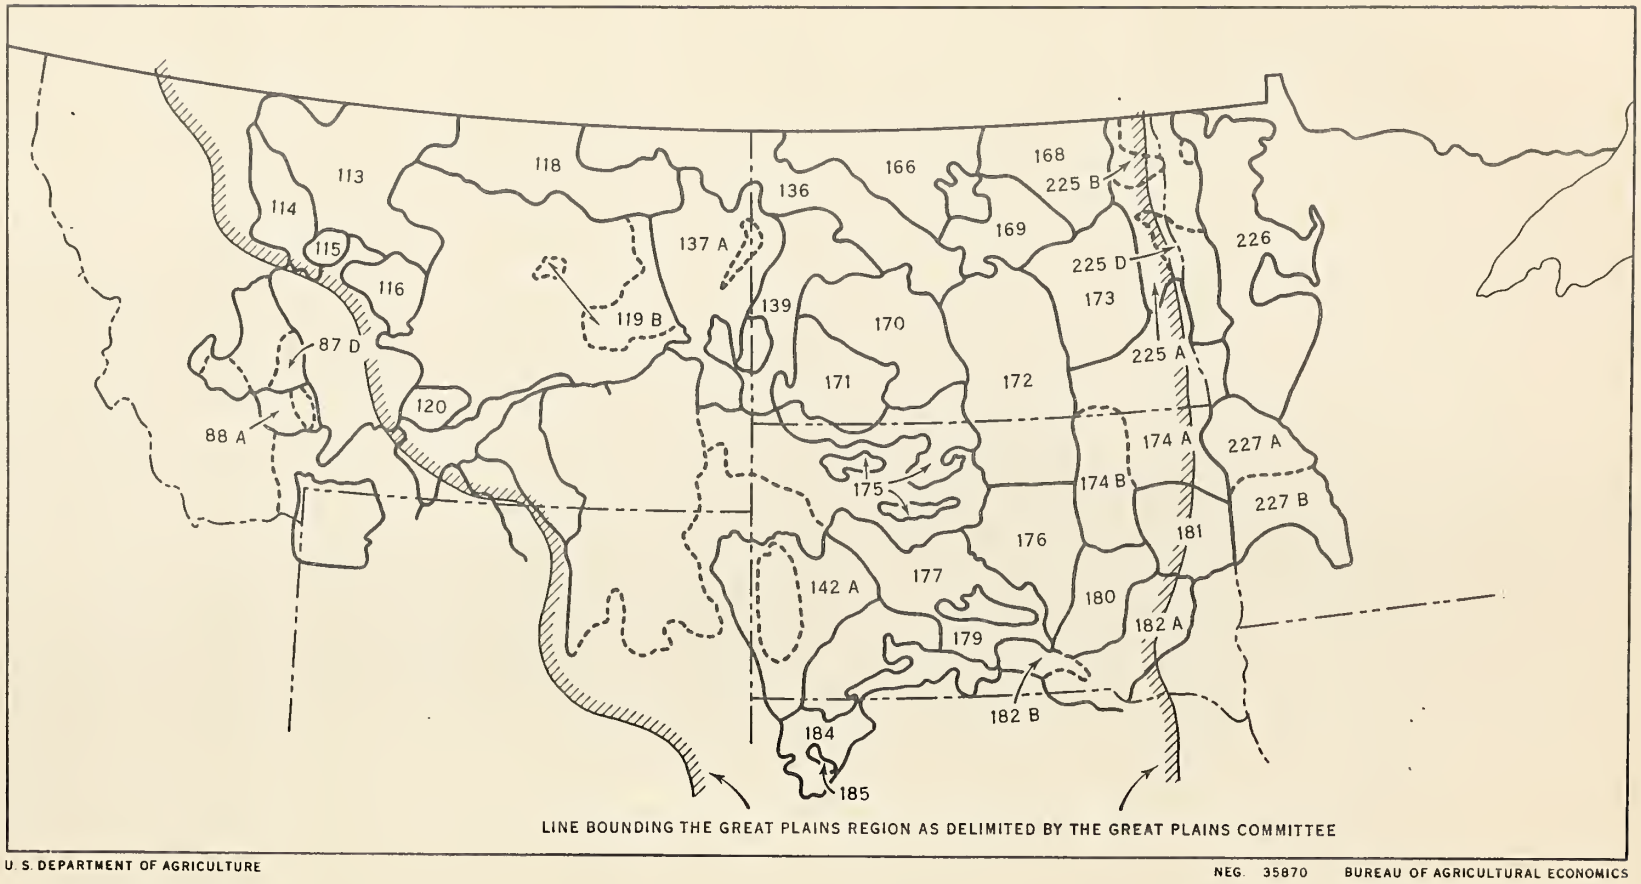

Figure 1. - Type-of-farming areas where study was made of the organization and crop production practices on grain farms (areas are those outlined in United States Department of Commerce, Bureau of the Census Bulletin "Types of Farming in the United States, 1930.")

(3) Utilization of Combined Harvester-Threshers and Cost of Harvesting Small Grains with a Combine (Northern Great Plains and Pacific Northwest, 1933).

(4) Cost of Operating Farm Motor Trucks on Grain Farms (Northern Great Plains and Pacific Northwest, 1933).

(5) Organization and Crop Production Practices on Grain Farms in Selected Areas of the Pacific Northwest.

The present report deals with the major wheat producing areas of the Northern Great Plains. It discusses (1) the physical and economic factors affecting agricultural production in the region; (2) wheat yields and frequency of damage to wheat from different causes; (3) the farm organization from the standpoint of size of farm, livestock kept, and the place of the different crops in the cropping system; (4) the practices employed in the production of different crops; (5) the duty of farm machinery; and (6) the labor and power involved in the production of crops.

The discussion is not concerned with the choice and combination of enterprises, but rather with the methods of production. An effort has been made to present the data in a way that will be of greatest use to those dealing with the problems of agricultural adjustment in the region, and an example is given of the application of the basic data to individual farms.

An inquiry as of June 1939 indicates that since this study was made, agricultural machinery developments have influenced certain aspects of the farm economy as portrayed by the farms under consideration.

There has been an appreciable increase in the use of farm tractors, especially in the more easterly areas of the region. As the acceptance of pneumatic tires has been unusually favorable it is probable that new tractors of the high-wheel type will be largely those mounted on rubber tires.

In the past 2 or 3 years small combines mounted on rubber have been used quite extensively in certain of the more easterly areas of North Dakota where formerly most of the grain was cut with the binder and threshed in a stationary separator. Aside from the use of the small combine, there has been no appreciable change in harvesting implements.

At different points in the report new machinery developments that have modified practices to any marked extent have been considered.

PHYSICAL FACTORS: THEIR RELATION TO LAND USE AND CROP YIELDS

As climate and other physical characteristics of a region are so closely related to land use and crop yields, an examination of these factors helps to give a better understanding of the status of the agriculture of the region.

Topography and Elevation

Topographic features of the arable lands favor large-scale farming operations in a considerable portion of the Northern Great Plains. Surface features of North Dakota and South Dakota westward to the Missouri River are characterized by undulating to gently rolling plains except in the Red River Valley of North Dakota which is generally level. The greater part of the area west and south of the Missouri River in the Dakotas is rolling to hilly. The Black Hills and the "Bad Lands" in southwestern South Dakota and the "Bad Lands" chiefly bordering the Little Missouri River in western North Dakota, are too rough to be generally suitable for crop production and are utilized chiefly for grazing purposes.

Approximately the western one-third of Montana lies in the Rocky Mountain region and the eastern two-thirds in the Northern Great Plains. The Plains area is characterized by undulating to gently rolling surface features broken by the stream courses of the Missouri and Yellowstone Rivers and their tributaries.

From east to west across the Northern Plains the elevation increases gradually. Most of the Red River Valley is less than 1000 feet in elevation, while at Dickinson in southwestern North Dakota the elevation is approximately 2500 feet above sea level. The elevation in Montana at Sidney, near the North Dakota line is slightly more than 3000 feet, while at Agricultural College in southwestern Montana it is nearly 5000 feet (fig. 2). 2/ Differences in elevation have an appreciable influence on temperature, dates of killing frosts and length of growing season, which in turn have their effect on crop production, particularly corn.

Soils

Where sufficient moisture is present soils of the Northern Great Plains are for the most part highly productive. In that part of the region north of the Missouri River in Montana and east of the Missouri in North Dakota and in South Dakota, the soils in general are the result of glacial accumulations, while the soils in other parts of the region are chiefly of residual origin.

In texture these soils vary from heavy clays to sands. In most areas fertile soils of good texture are available for cultivation.

These soils were, for the most part, developed under a grass cover. There are a series of soil belts running north and south. The most easterly of these soil belts are characterized by dark soils. From east to west the soils become lighter in color, as the density of the grass cover lessens and the rainfall decreases. The dark color of the soil is due to an accumulation of organic matter derived from the decay of vegetable matter. 3/

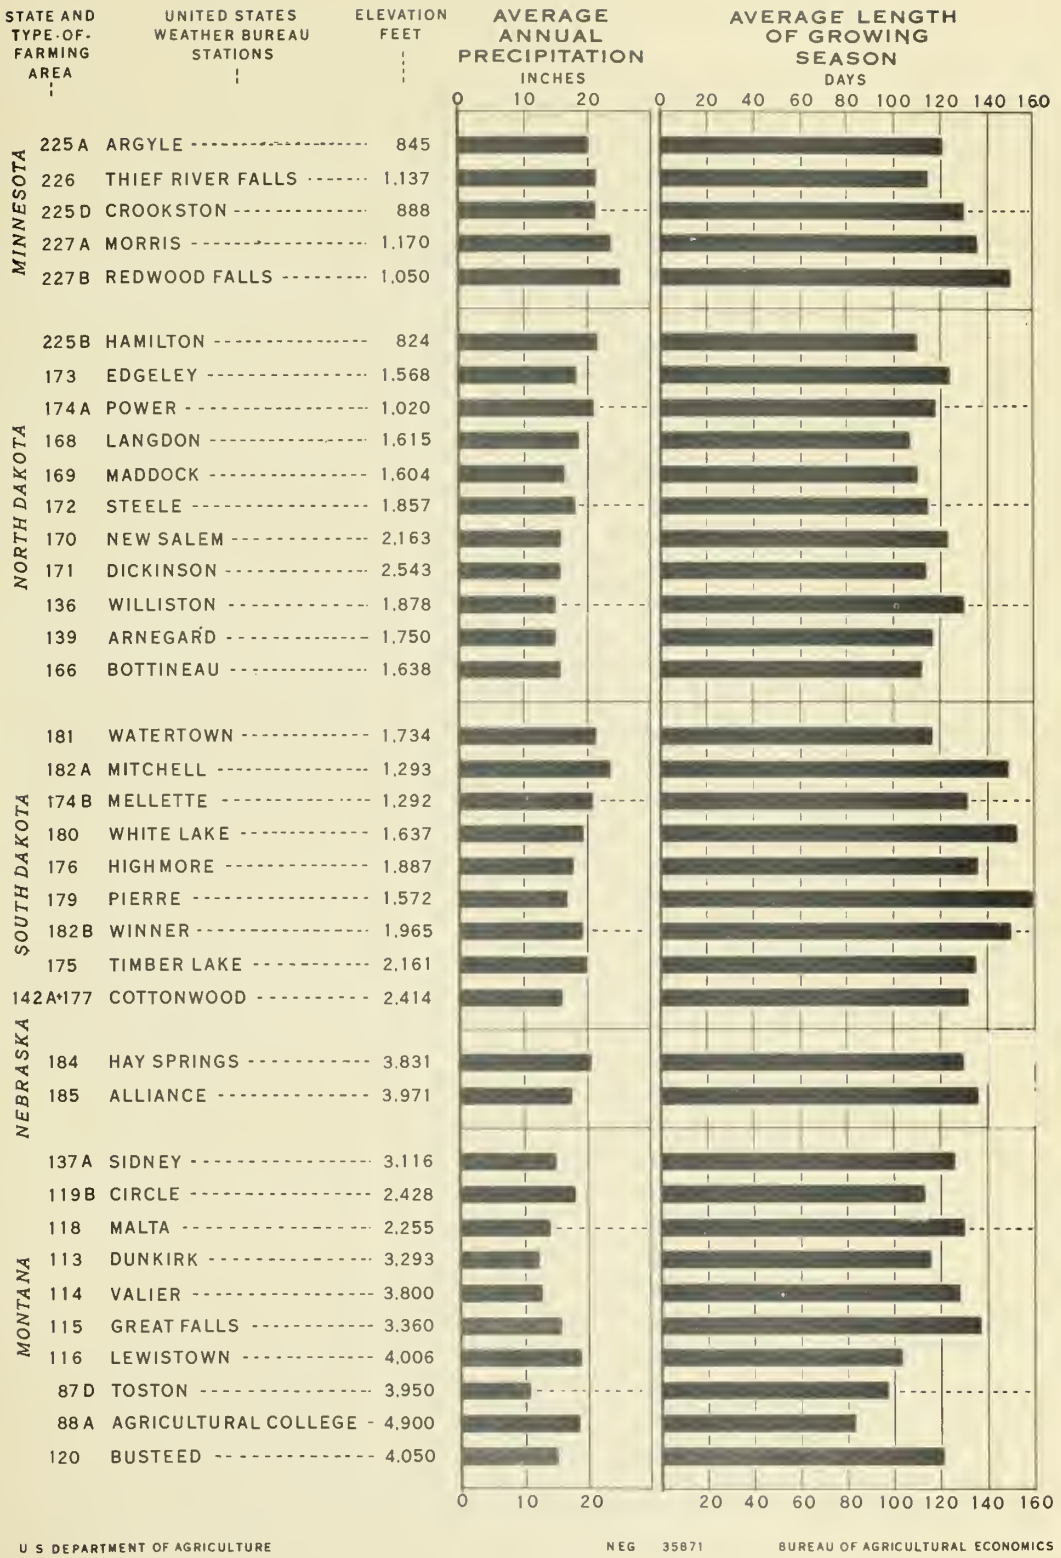

Figure. 2. - Elevation, precipitation, and length of growing season at selected United States Weather Bureau Stations

Climate

The climate of the region is characterized by rather wide extremes of temperature, a dry atmosphere, much sunshine and a moderate to low rainfall.

The temperature during the summer months may reach 100 degrees or more. During periods of prolonged high temperature, the increased evaporation seriously depletes the moisture supply and causes severe damage to crops. In addition, the characteristic high wind velocity heightens the losses due to high temperatures and evaporation. Furthermore the ground may become frozen early, and if the winter is severe, may remain frozen, so that subsequent rains run off without supplying moisture to the soil. On the other hand, an early and plentiful blanket of snow may protect and moisten the soil. A favorable factor which results in the rapid growth of plants is the long hours of sunshine, especially during the growing season.

Climatic conditions, as portrayed by records of annual precipitation and length of growing season at selected United States Weather Bureau Stations, are shown in figure 2. Annual precipitation and length of growing season are much more favorable in the eastern areas than in other parts of the region. The average annual precipitation ranges from less than 12 inches in south-central Montana to approximately 25 inches in southwestern Minnesota. It does not exceed 20 inches except in the eastern parts of the region. The growing season is more than 150 days in the southeastern areas, whereas in certain areas of Montana it is less than 100 days. A favorable factor is that the greatest precipitation occurs in May, June, and July, the critical period in plant growth for small grain crops. In years of average or better than average annual precipitation and where the seasonal distribution is favorable it is usually adequate to produce a satisfactory yield of the drought resistant small grains. The southeastern part of the region, however, is the only area where rainfall and length of growing season are usually adequate to produce a satisfactory crop of corn for grain.

Variations in annual precipitation from year to year, together with fluctuations in its seasonal distribution are large factors in determining whether there will be a satisfactory yield or a crop failure. The Weather Bureau record at Williston, northwestern North Dakota, may be taken to illustrate the variations in the annual and seasonal distribution of rainfall. At this station there have been a number of years of low rainfall as well as an abnormal distribution during the critical period of the growing season, May, June and July. Over a 42 year period the average annual rainfall has been 14.8 inches but in 12 of these years it has been less than 13 inches. Approximately 67 percent of the rainfall normally comes during the growing season from May to September and 50 percent occurs during the critical period, May, June and July. Over the 15-year period from January 1921 to December 1934, the variation in May has been from .47 to 4.69 inches; in June from 1.24 to 6.98 inches; and in July from .5 to 6.07 inches.

WHEAT YIELDS

As a measure of the possibilities of different areas for wheat production, not only the long time average yield of wheat but the frequency of occurrence of good and poor crops are of importance. Long time average wheat yields of farmers interviewed, calculated from their reports of good and poor yields, are shown in table 1. These yields are somewhat higher than county averages and perhaps more nearly represent the production possibilities of the better farms and farmers than of the average.

Farmers' estimates indicate less variability in wheat yields in western Minnesota and eastern North Dakota, than in most other areas. Farmers in these areas reported few crop failures and moderately high yields. A productive soil and the practice of growing wheat in west-central Montana on summer fallowed land is a factor in the relatively high yields of wheat reported for this area.

The causes of damage to wheat yields, as reported by farmers interviewed, are given in table 2. They reported that deficient moisture had reduced wheat yields more than any other one cause. While drought was the greatest single factor influencing wheat yields, this cause was of lesser importance in western Minnesota and eastern North Dakota than in the other areas. According to farmers' estimates, total loss of the wheat crop in these areas, because of drought, varied from 0 to approximately 4 percent of the time that they had been producing wheat, while in areas represented in western North Dakota this variation was from approximately 6 to 11 percent of the time.

Plant disease, mainly black stem rust, ranked second as a factor in reducing wheat yields in western Minnesota and in the more easterly areas of North Dakota and South Dakota. In the higher and drier areas, such as the western Dakotas and Montana, the damage from rust was not particularly severe.

Grasshoppers and hail caused some damage in all areas. Hail damage is generally of a local nature. It may cause damage in a certain location one year, and in another locality in another year.

ORGANIZATION OF FARMS STUDIED

Because of the influence of large power equipment, the farms have been classified on the basis of those with and those without tractors.

Size of Farms and Division of Farm Area of Farms with and Without Tractors

In this region topography plays a leading part in determining the relative acreage of permanent pasture and cropland on dry land grain farms. In western Minnesota and in about the eastern half of the Dakotas the proportion of the farm area in cultivation was greater than in the western

Dakotas and in certain areas of Montana, where the land is less suited to crop production, because of less productive soil and the tendency toward a more rolling to hilly toeography.

The proportion of the total farm land in cultivation (cropland and summer fallow land) for both farms with and without tractors was quite similar for a given area. For all farms with tractors, cropland represented 52 percent; summer fallow 9 percent; and permanent pasture and other land 39 percent of the total farm area. For all farms without tractors the division was: Cropland 48 percent; summer fallow 4 percent; and permanent pasture and other land 48 percent (figs. 3 and 4).

The proportion of farms in each size group, based on crop acreage per farm, for those with and without tractors is shown in figures 5 and 6. In all areas the crop acreage on farms where tractors were used exceeded that on farms using only horses for field work. With the tendency toward the greater use of tractors in areas of large wheat farms, the crop acres per farm average 120 percent larger on farms with than without tractors. Approximately 70 percent of the surveyed farms with tractors were under 561 acres; 50 percent were under 401 acres; and 18 percent were under 241 acres.

In contrast with the general tendency for relatively large farms to have tractors is the tendency for small farms to be without tractors. Farms without tractors tend to be in the 240 and under and in the 241-400 acre size groups, with the greater number in the smaller group. Approximately 97 percent of all farms without tractors were under 561 acres; 91 percent were under 401 acres; and 58 percent were under 241 acres.

Tractors were used in all of the grain producing areas in the Northern Great Plains. They were the chief source of power for field work on many of the larger farms in the more westerly areas. On the smaller general farms in the eastern areas of the region, horses were used for certain kinds of farm work, and on many of these farms they were the only source of power for field work.

The proportion of the farms with tractors, according to this sample, varied from 25 percent in a general farming area of western Minnesota to 100 percent in one of the wheat areas of Montana.

In western Minnesota and in the eastern part of North Dakota and South Dakota about 50 percent of the farms had tractors; in the central and western parts of the Dakotas about 70 percent; and in Montana and northwestern Nebraska about 80 percent were farms with tractors. For the entire region 69 percent of the farmers enumerated had tractors.

Distribution of Tractors of Different Types and Sizes According to Crop Area per Farm

The number of tractors by type and size, according to acreage in crops on farms reporting tractors, is given in table 3. In this region there did not appear to be any decided relationship between crop acreage per farm and size of tractor. There was some tendency for the larger tractors, especially

those of the track-laying type, to be on the larger farms but a greater tendency for those farmers who are operators of large acreages to operate two or more tractors of medium size rather than the larger tractor.

For the most part, farmers with about 400 crop acres or less per farm had only one tractor, whereas on quite a large percentage of the farms with crop acreage in excess of this more than one tractor was owned. Fifty-five percent of all tractors enumerated were on farms of 500 crop acres or less, 32 percent were on farms of 501 to 1000 crop acres, and 12 percent were on farms of over 1000 crop acres.

Tractors of 15- to 17-drawbar horsepower, of the ordinary high-wheel type, were the most common and were followed in order by those of 8- to 12-drawbar horsepower. General purpose tractors of 9- to 12-drawbar horsepower were quite common in the areas of South Dakota and western Nebraska where row crops are grown to a considerable extent. Tractors of the track-laying type were reported only in Montana.

Livestock

The numbers of different classes of livestock on surveyed farms, in most areas, were small. The intensity of the livestock enterprise is indicated by the numbers of livestock per 100 acres of farm land (fig. 7).

Milk cows were reported in greatest numbers in the Red River Valley of North Dakota and Minnesota and in the eastern areas of South Dakota, where alfalfa is grown to a considerable extent. The hog enterprise was of greatest importance in southwestern Minnesota and in the eastern areas of South Dakota where a substantial acreage of corn is grown. Beef cattle were of some importance in central South Dakota and in certain areas of Montana.

The introduction of large units of power equipment has resulted in a heavy displacement of work stock and has enabled farmers to produce crops with a minimum of labor. The numbers of work stock per 100 acres of cropland for farms with tractors varied, as between areas, from .25 to 2.5, while on horse-operated farms the variation was from 1.3 to 3.9. The average number for all horse-operated farms was 2.7 per 100 acres of cropland compared with an average of 1 for all farms with tractors (fig. 8).

The numbers of various kinds of livestock per farm are shown by type-of-farming areas in appendix table 26.

Crops Grown and Their Place in the Cropping System

The agriculture of the arable lands of the region may be classified as primarily a cash grain type-of-farming with wheat the major crop. On surveyed farms the proportion of the crop area utilized for the production

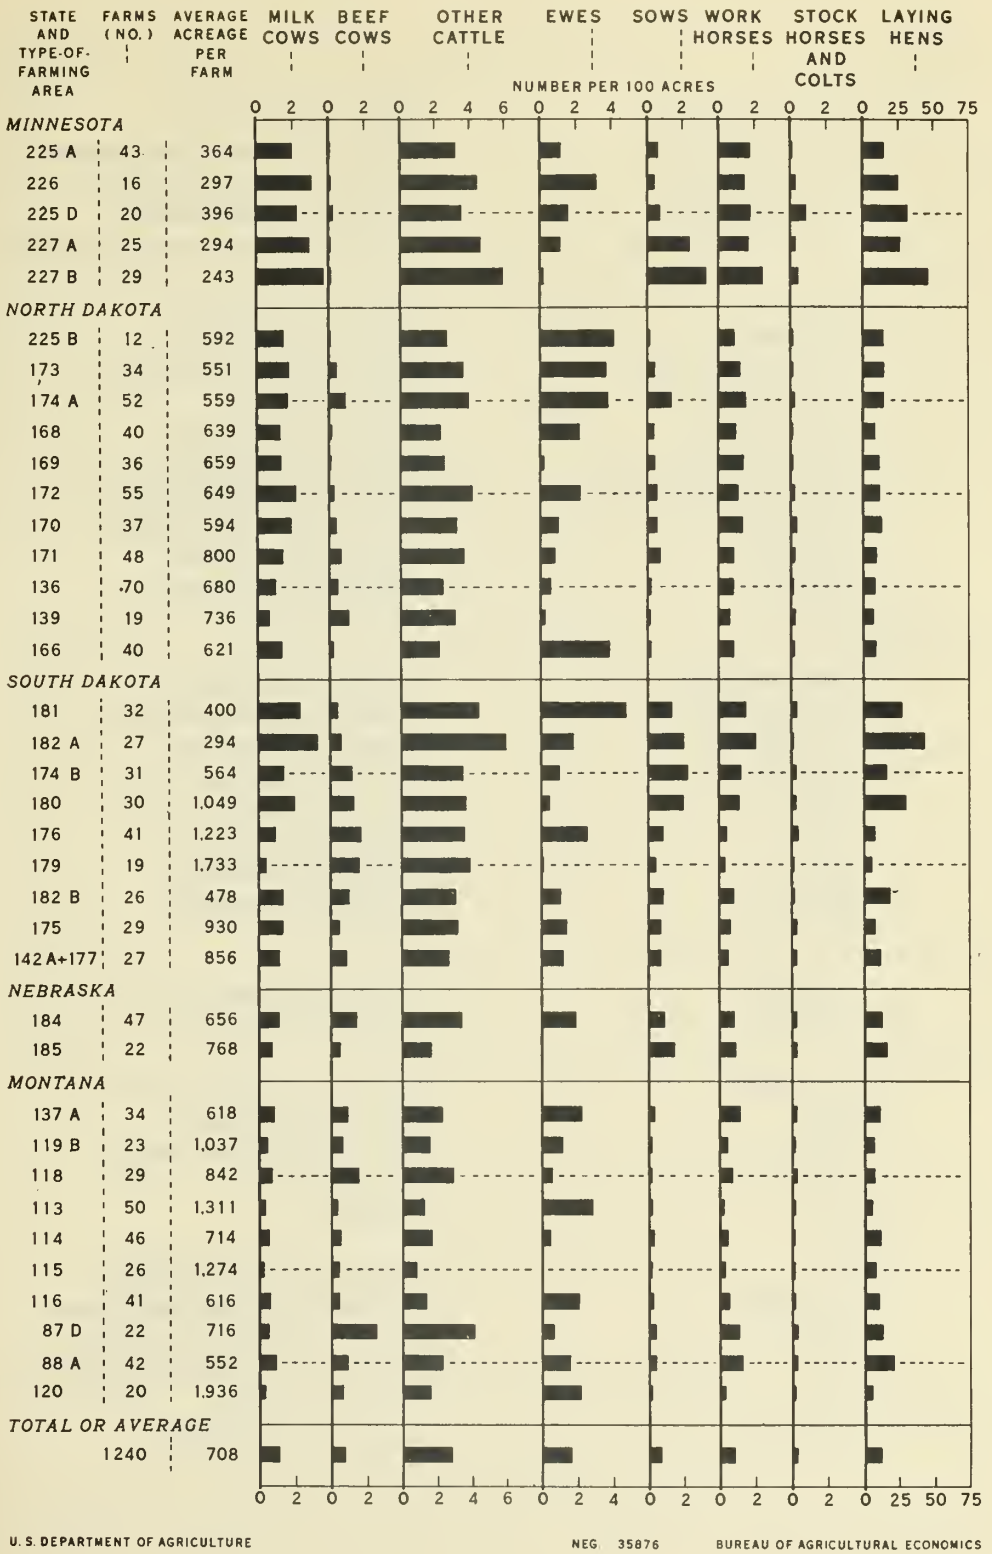

Figure 7. - Numbers of livestock per 100 acres of farm land by type-of-farming areas, Northern Great Plains, 1933

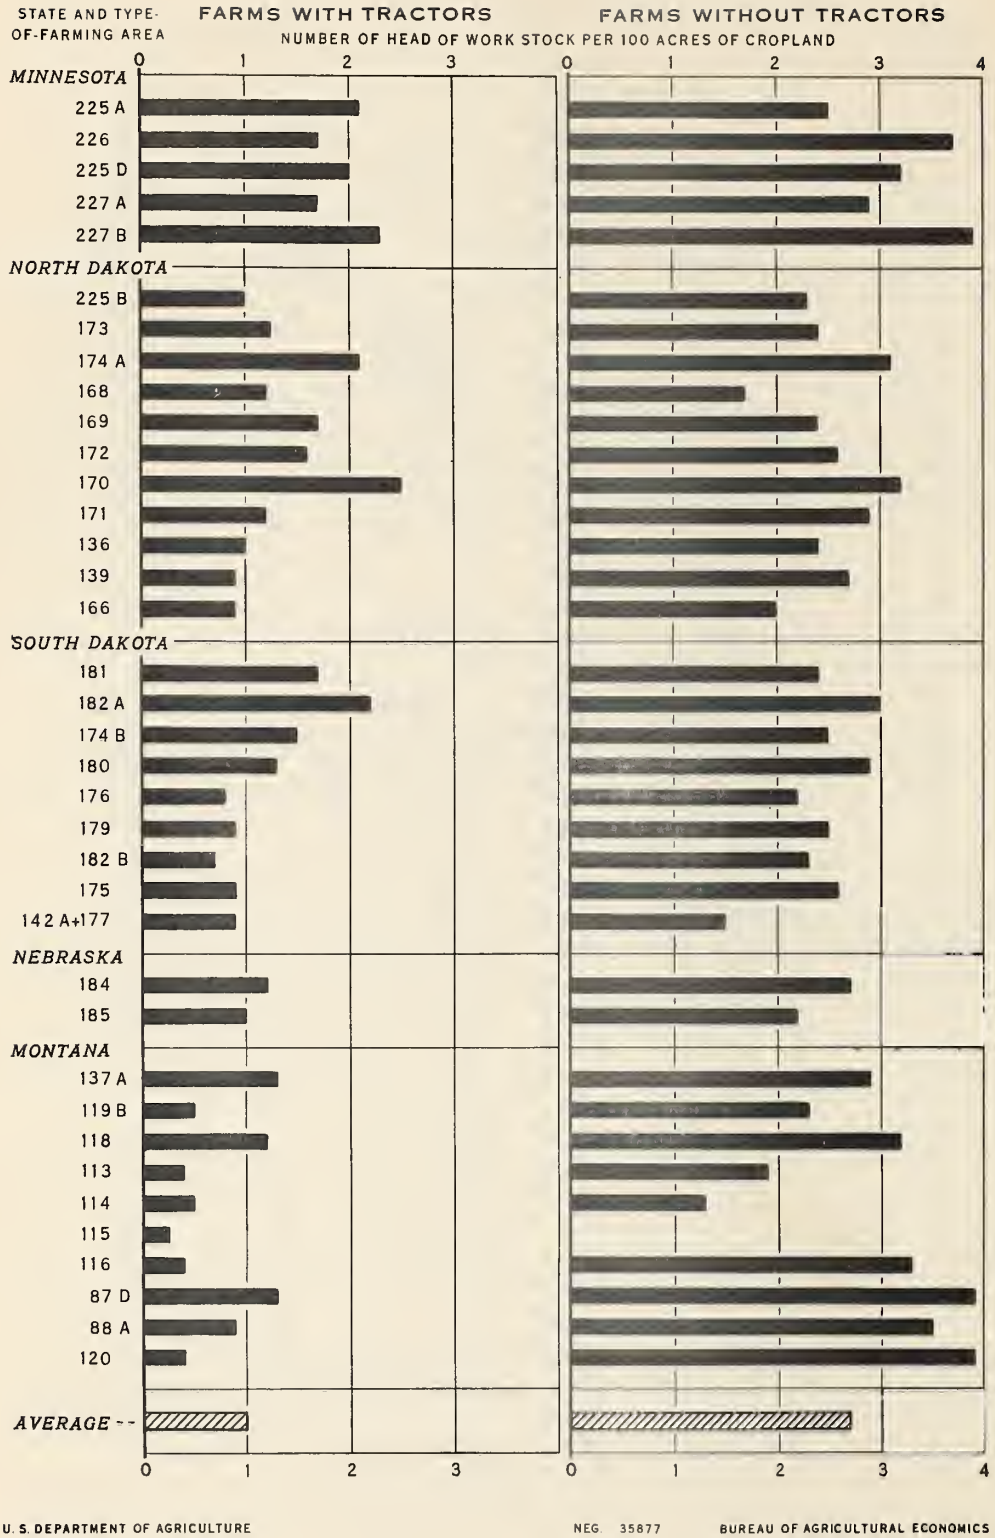

Figure 8. - Numbers of head of workstock per 100 acres of cropland by type-of-farming areas, Northern Great Plains, 1933

of different crops varied to a considerable extent as between different type-of-farming areas (figs. 9 and 10).

Proportionately more of the total crop area was devoted to wheat and summer fallow in west-central Montana than in other areas studied. Proceeding eastward, a rather decided change in crop combinations begins to appear. Instead of alternating wheat with summer fallow, the common practice was to grow wheat in combination with corn, oats and barley. In eastern Montana and northwestern and north-central North Dakota, wheat was the principal crop grown, with moderate acreages of oats, barley and corn. These crops with summer fallow accounted for most of the crop acreage. In southwestern North Dakota, western South Dakota and northwestern Nebraska, wheat was still the dominant crop, but the acreage devoted to corn, oats and barley showed a considerable increase over that of eastern Montana and northwestern and north-central North Dakota. In south-central North Dakota and central South Dakota, wheat still held first rank but acreages of oats and barley and especially corn in central South Dakota were of increasing importance. In eastern North Dakota and South Dakota and in western Minnesota, wheat occupied from 15 to 50 percent of the crop area, with barley, oats and corn making up most of the balance.

The greatest concentration of the corn acreage was in eastern South Dakota and southwestern Minnesota. In addition, alfalfa, sweet clover, and flax were of considerable importance on some farms, especially in western Minnesota. The distribution of the crop acreage per farm for surveyed farms, with and without tractors, is given by type-of-farming areas in appendix tables 27 and 28.

Spring wheat was alternated with summer fallow on 70 percent or more of the spring wheat acreage on surveyed farms in Areas 114, 83A and 87D of Montana. In other Montana areas, from 20 to 50 percent of the spring wheat acreage was alternated with summer fallow and the remainder largely seeded after small grains (fig.11).

In Areas 139, 166, 168 and 173 of North Dakota, 25 to 40 percent of the spring wheat acreage was alternated with summer fallow and the remainder almost entirely seeded after small grains. In other areas of North Dakota, from 60 to 90 percent of the spring wheat acreage was seeded after small grains and the remainder largely seeded after row crops.

In the Nebraska areas, 70 percent or more of the spring wheat acreage was seeded after row crops and the remainder seeded after small grains.

In Areas 180 and 182A of South Dakota, 90 percent or more of the spring wheat acreage was seeded after row crops and the remainder seeded after small grains. In Areas 181 and 175 of South Dakota, 80 percent or more of the spring wheat acreage was seeded after small grains and the remainder seeded after row crops. In other areas of South Dakota, from 45 to 55 percent of the spring wheat acreage was seeded after small grains and the remainder seeded after row crops.

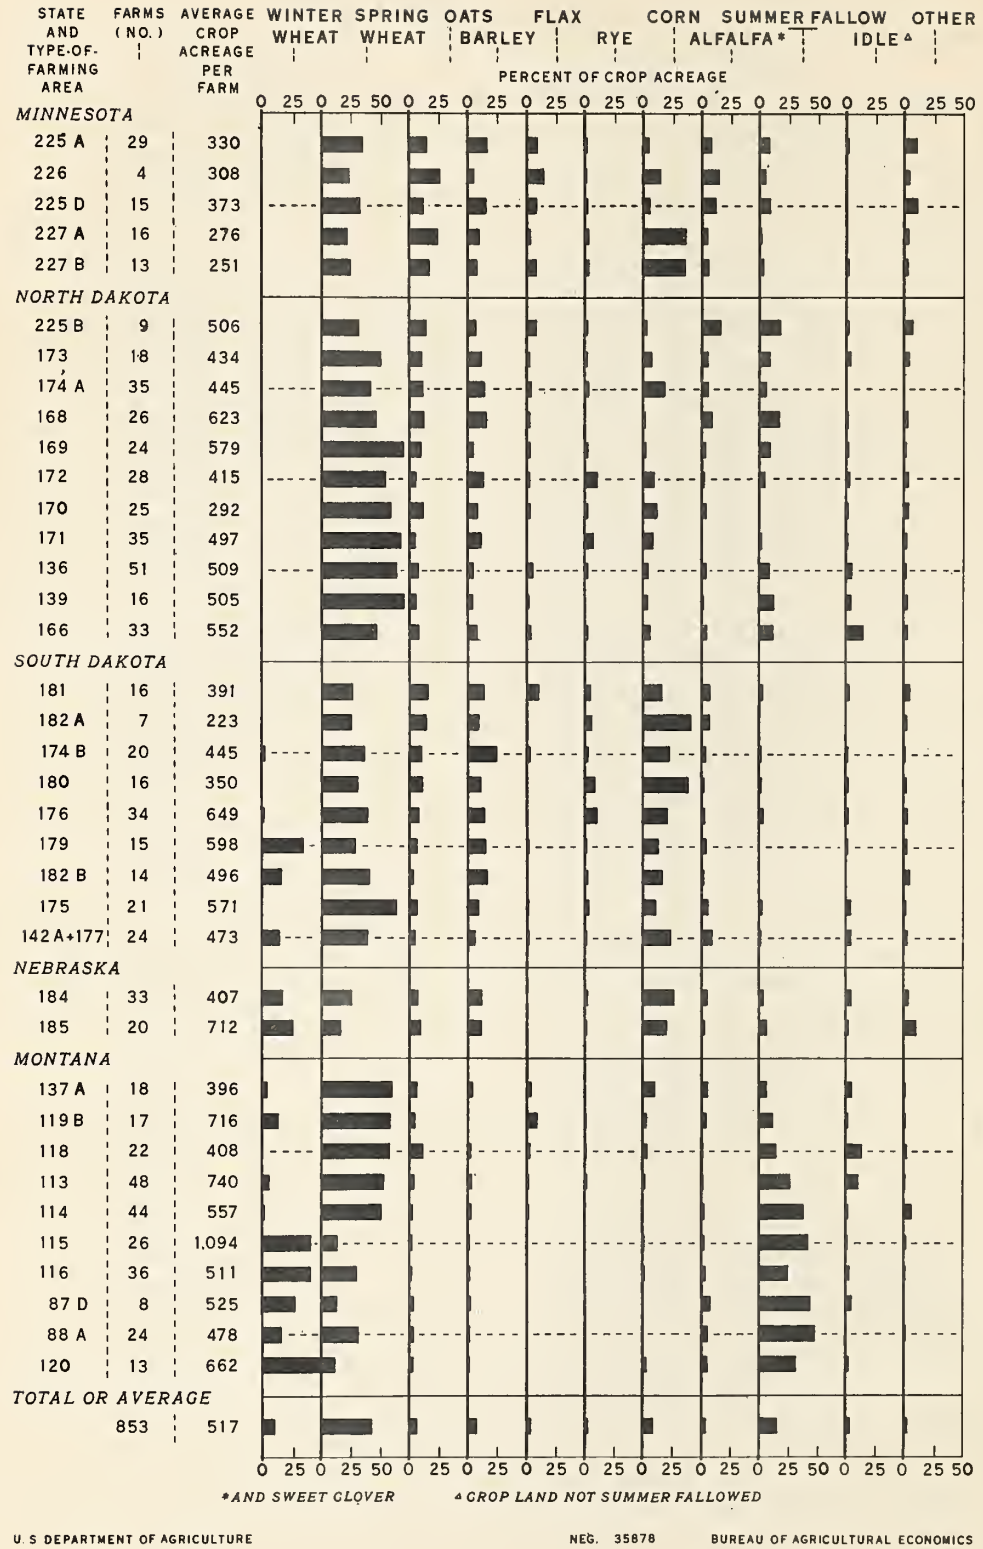

Figure 9. - Farms with tractors: Proportion of crop acreage in specified crops for surveyed farms by type-of-farming areas, Northern Great Plains, 1933

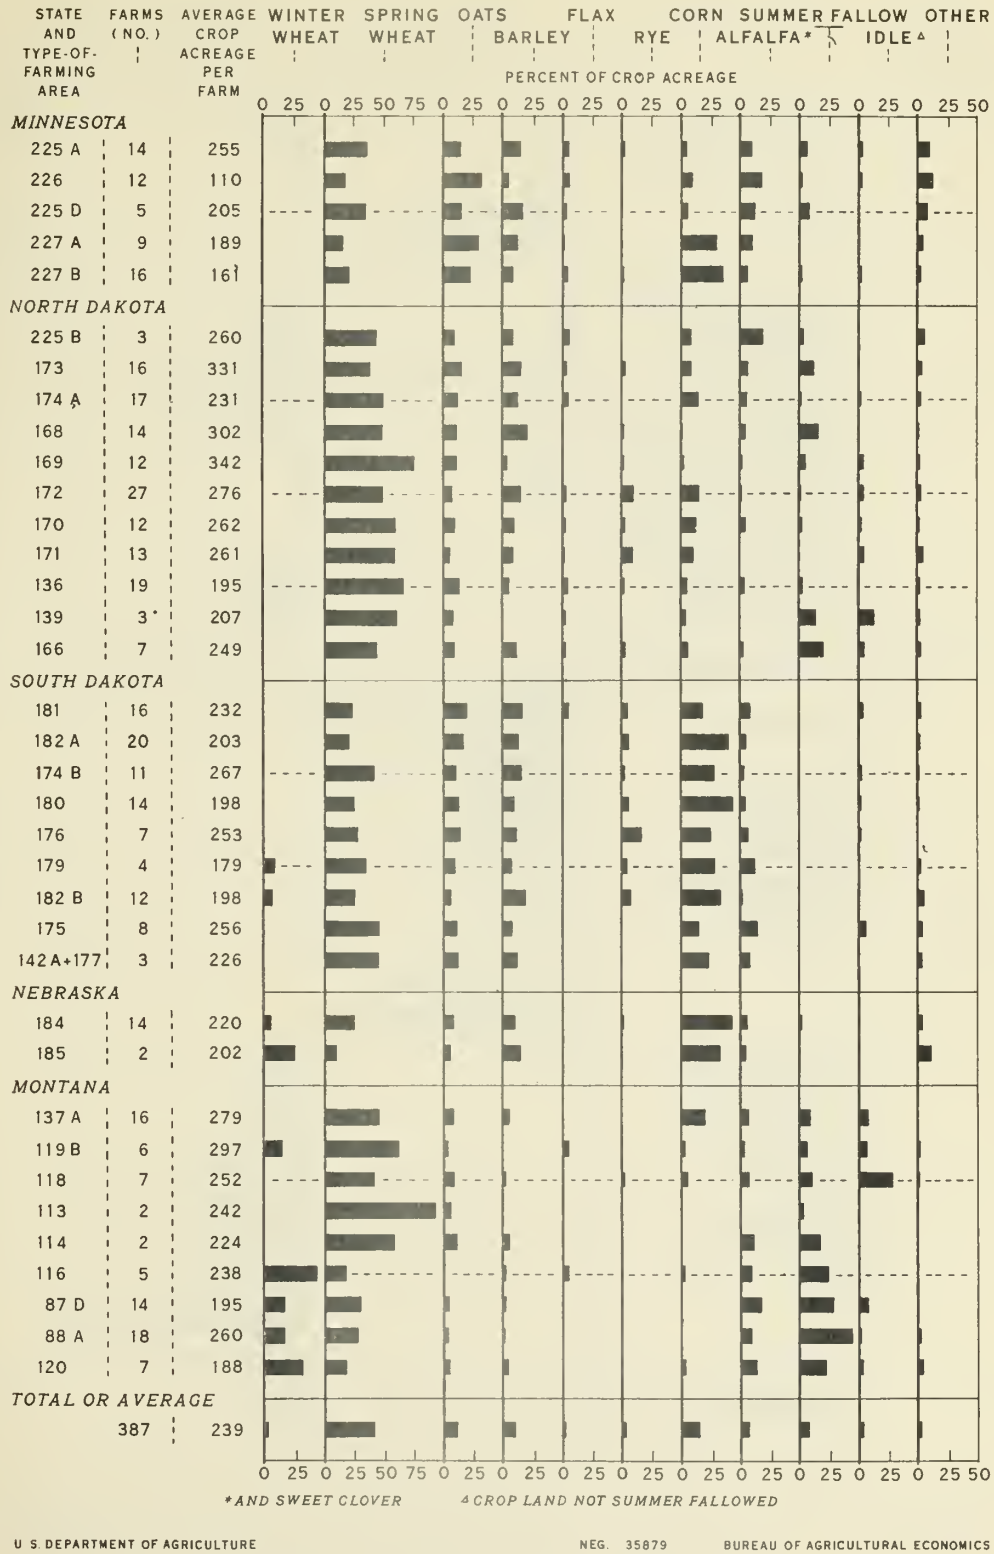

Figure 10. - Farms without tractors: Proportion of crop acreage in specified crops for surveyed farms by type-of-farming areas, Northern Great Plains, 1933

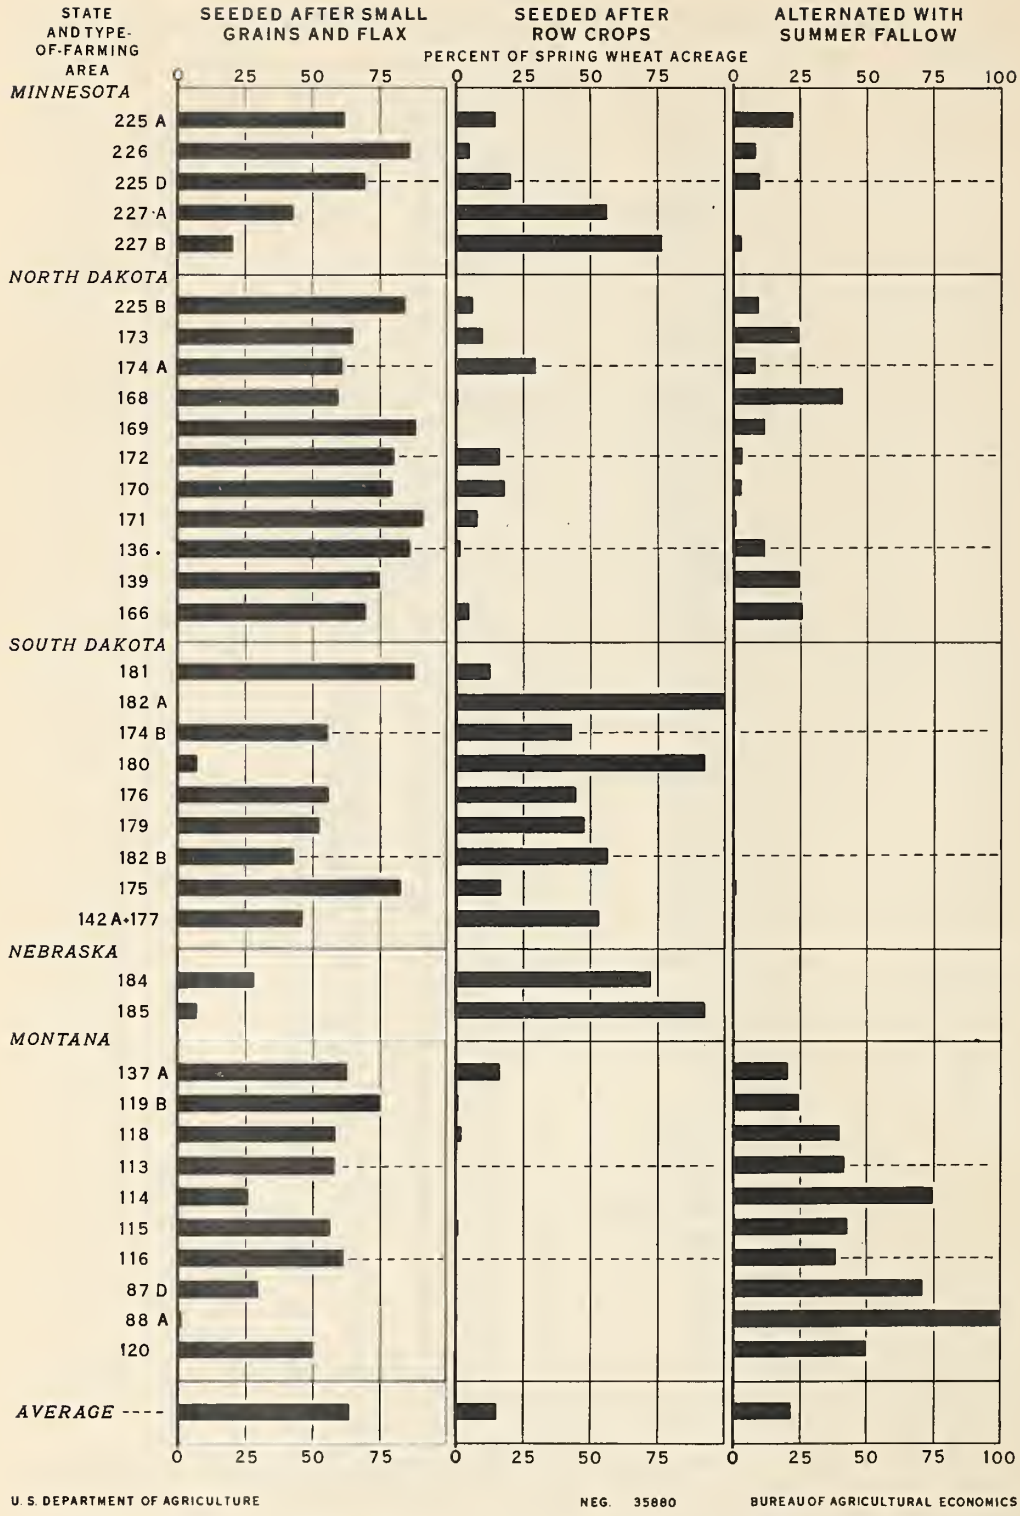

Figure 11. - Proportion of spring wheat acreage seeded after small grains, after row crops and alternated with summer fallow on surveyed farms by type-of-farming areas, 1933

In southwestern Minnesota, 55 percent or more of the spring wheat acreage was seeded after row crops and the remainder largely seeded after small grains. In other areas of western Minnesota 65 percent or more of the acreage was seeded after small grains and the remainder largely seeded after row crops.

Winter wheat was not grown to any extent except in west-central Montana, northwestern Nebraska and in south-central South Dakota. In west-central Montana, from 50 to 100 percent of the winter wheat acreage was alternated with summer fallow. In those areas of west-central Montana where winter wheat was not entirely alternated with summer fallow the remainder was seeded after small grains. In northwestern Nebraska and south-central South Dakota, 65 percent or more of the winter wheat acreage was seeded after small grains and the remainder largely seeded after row crops.

Oats and barley were grown on most surveyed farms except in Montana where the acreage of barley, especially, was very limited. For a given area the proportion of the acreage that was seeded after small grains and flax, seeded after row crops, and alternated with summer fallow was quite similar for each of these crops. The proportion of the oats acreage seeded after small grains and flax, seeded after row crops, and alternated with summer fallow on surveyed farms is shown in figure 12.

The oats crop in Areas 114 and 88A of Montana was alternated with summer fallow on 45 percent or more of the oats acreage and the remainder seeded after small grains. In Area 137A of Montana, about two-thirds of the oats acreage was seeded after small grains and one-third seeded after row crops. In other areas of Montana, 70 percent or more of the oats acreage was seeded after small grains and the remainder largely alternated with summer fallow.

In northwestern Nebraska, about two-thirds of the oats acreage was seeded after row crops and one-third seeded after small grains.

In South Dakota, 65 percent or more of the oats acreage in Areas 181, 174B and 175 was seeded after small grains and the remainder after row crops. In Areas 142A and 177 of South Dakota about one-half of the oats acreage was seeded after small grains and about one-half after row crops. In other areas of South Dakota 60 percent or more of the oats acreage was seeded after row crops and the remainder seeded after small grains.

In North Dakota, 70 percent or more of the oats acreage was seeded after small grains and the remainder largely seeded after row crops.

In Southwestern Minnesota, about two-thirds of the oats acreage was seeded after row crops and one-third seeded after small grains. In other areas of western Minnesota 90 percent or more of the oats acreage was seeded after small grains and the remainder seeded after row crops.

In most areas, on surveyed farms, flax was grown to only a limited extent. In Areas 225A of Minnesota and 225B of North Dakota, a limited acreage of flax was grown on summer fallow land, while in southwestern Minnesota and in Area 171 of North Dakota, a small acreage was grown after row crops.

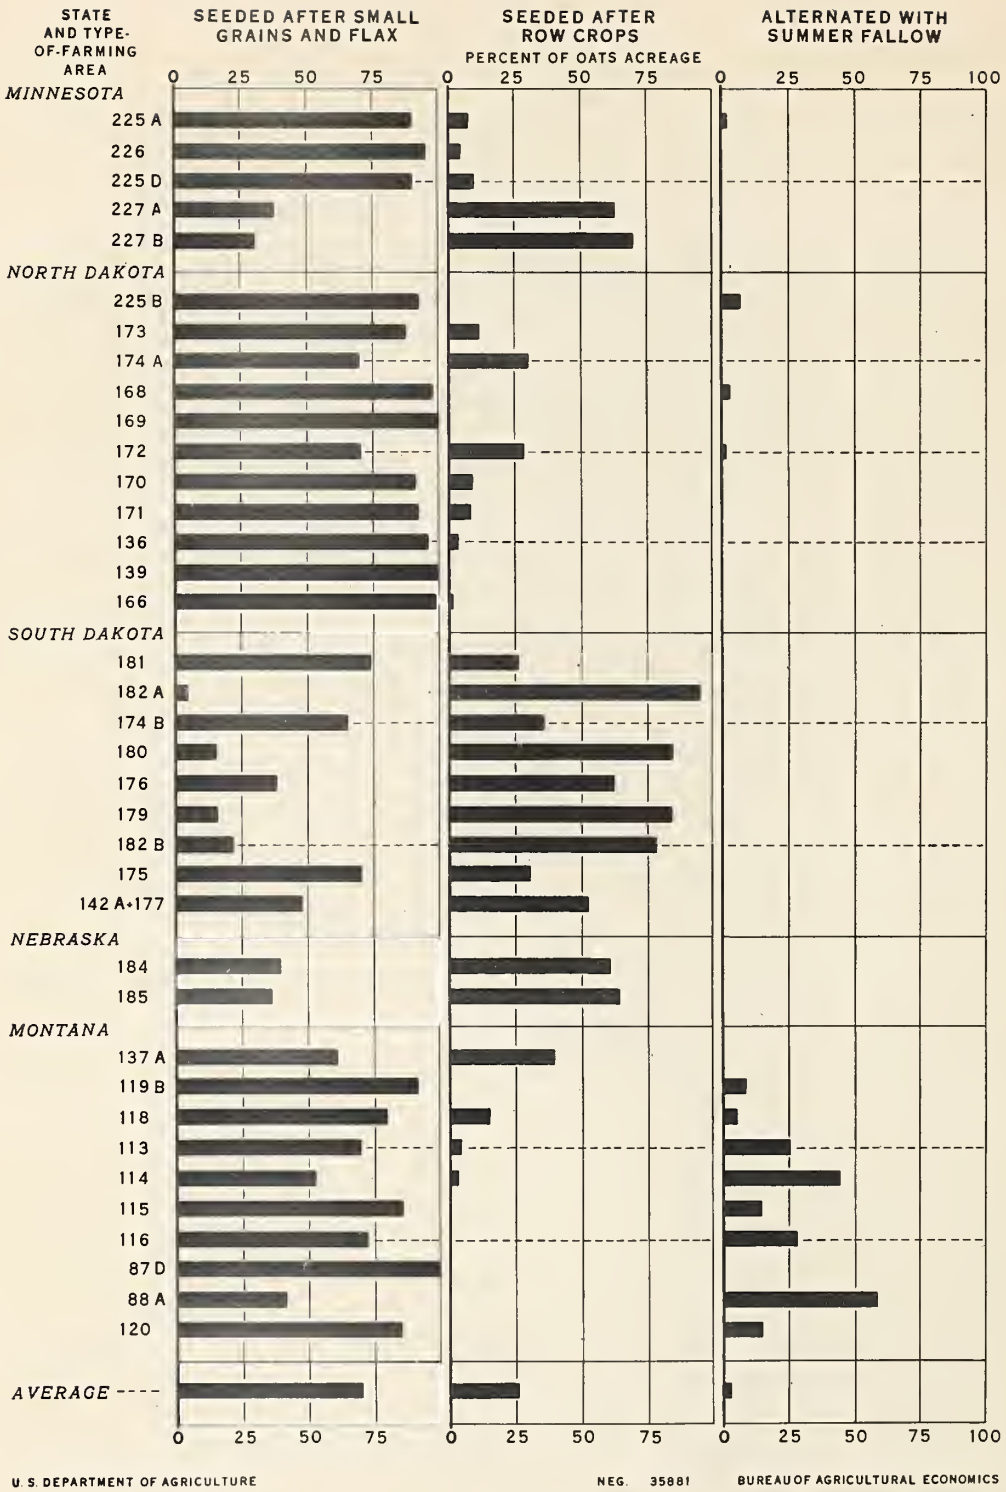

Figure 12. - Proportion of oats acreage seeded after small grains, after row crops and alternated with summer fallow on surveyed farms by type-of-farming areas, 1933

In Area 170 of North Dakota some flax was grown after row crops and on new land. In other areas 75 percent or more of the flax acreage, on surveyed farms, was seeded after small grains.

The corn acreage was all represented by land that had been in a small grain or flax crop the previous year.

SEEDBED PREPARATION AND PLANTING

Because of variations in the number and kind of operations performed on different crops, the implements employed in seedbed preparation and planting field crops are shown according to their use on individual crops in different areas. The size of implement and motive power used in seedbed preparation for small grains, flax and corn and for seeding small grains and flax has not been shown by individual crops, since in most cases, an implement of a given size drawn by a designated power unit is used on all of these crops that are grown on a given farm. This simplifies the discussion of tillage implements common to several crops and the power used to draw them.

Operations Performed in Seedbed Preparation and Planting Field Crops According to their Place in the Cropping System

The implements used in tillage practice varied both between and within areas. Soil conditions, topography, and quantity and seasonal distribution of rainfall, differ too widely to make it possible to handle the land in a uniform manner. Furthermore, the operations performed are greatly influenced by whether the crop in question follows a drilled crop, an intertilled crop, or is planted on summer fallowed land.

In general, the operations performed in preparing a suitable seedbed are greatest where the summer fallow method of crop production prevails, somewhat less when following a drilled crop, and least when grown after an intertilled crop (mostly corn).

The ground may be plowed either in the fall or spring. In western Minnesota, eastern North Dakota, and eastern South Dakota, fall plowing was the rule for spring planted small grains and flax where these crops followed a small grain, flax, or row crop. Since spring wheat is the first crop planted in the spring as much plowing is done in the fall as is possible. Farmers in these areas practice fall plowing for spring wheat relatively more than for oats and barley. Fall plowing is done during the period after harvest until the ground freezes. In the central and western Dakotas and in Montana, spring plowing for spring planted small grains and flax was the rule.

Small Grains and Flax Grown After Small Grains and Flax

After a drilled crop such as wheat, oats, barley or flax, the land in usually more or less weedy and the top soil is hard. Therefore considerable work is usually necessary in preparing a proper seedbed. The usual operations in preparation of seedbed and seeding wheat, oats, barley and flax where grown on stubble land are shown in table 4.

Table 4 - Common practices employed in seedbed preparation and seeding small grains and flax where grown after small grains and flax, by type-of-farming areas, Northern Great Plains 1/

1/ Tillage and planting implements are abbreviated as follows: MP=moldboard plow, 1-way = vertical disk plow, DP = disk plow, H = spike-tooth harrow, Spt = spring-tooth harrow, D= disk harrow, P = packer, L = level, Duft = duckfoot cultivator, Dr = drill, End-gate = end-gate seeder.

Plowing with the moldboard plow was a common practice in all areas of western Minnesota and eastern North Dakota. In certain areas of west-central Montana, the one-way vertical disk plow was commonly used in the initial operation in preparing the seedbed. The disk harrow was substituted for the plow to a considerable extent in most areas except those in western Minnesota and in eastern North Dakota. Drilling in stubble was a common practice in most areas where winter wheat was grown.

Where land was plowed with the moldboard plow common practice consisted of plowing 1 time, spike-tooth harrowing 1 or 2 times and drilling. In some areas the disk harrow, spring-tooth harrow or duckfoot cultivator was used in addition to the spike-tooth harrow. Moldboard plowing in a combination hitch with another tillage implement was a common practice in the central and western Dakotas and in Montana.

A common practice, where the one-way vertical disk plow was used, consisted of one-way plowing, spike-tooth harrowing 1 or 2 times, and drilling. On some farms one-way plowing and spike-tooth harrowing were done as one operation, while on other farms, drilling and spike-tooth harrowing were done in combination.

Where the disk harrow was substituted for the plow in the preparation of the seedbed, a common practice was to disk harrow 1 or 2 times and drill. Some farmers disked and drilled in a single operation, while others disked 1 time, spike-tooth harrowed 1 time and drilled.

In areas where drilling was the first operation, the land either received no other preparation or it was spike-tooth harrowed 1 or 2 times.

Where small grains were broadcasted with an end-gate seeder, it was a common practice to disk harrow 1 or 2 times and spike-tooth harrow 1 time.

Corn Grown After Small Grains and Flax

Practically all corn was grown after small grains or flax. The usual practices in preparing the seedbed and planting corn that follows these crops are shown in table 5.

In south-central South Dakota, northwestern Nebraska and to some extent in eastern Montana corn was planted with a lister planter, a machine which opens up the furrow and plants the seed in the open furrow in one operation. Where this practice was followed a common way was to disk harrow 1 time, lister plant 1 time, spike-tooth harrow 1 or 2 times and cultivate 2 or 3 times with a lister cultivator.

In western Minnesota, North Dakota, central Montana, and in South Dakota except in the south-central part, corn was surface planted. When planted for grain it is commonly check-planted, when intended for fodder or silage it is usually drill planted. Where corn was surface planted most farmers, as the initial operation in preparing the seedbed, plowed the land with a moldboard plow. In the Red River Valley of Minnesota and North Dakota

1/ Tillage and planting implements are abbreviated as follows: MP = moldboard plow, H = spike-tooth harrow, Spt = spring-tooth harrow, D = disk harrow, P = packer, Duft = duckfoot cultivator, SP = surface planter, LP = lister planter, Cult = cultivator.

the use of the disk harrow, duckfoot cultivator or spring-tooth harrow was quite common, but these tillage implements were not used on corn land to any great extent in other areas. Their use in the Red River Valley may be attributed to the facts that much of the land is a clay loam and that weed-infestation is perhaps more severe here than in most other areas. Spike-tooth harrowing was common in all areas on surface planted corn land. Most farmers spike-tooth harrowed 1 or 2 times after planting. In areas where lister planting was common somewhat less spike-tooth harrowing was done after planting than where surface planting was the rule.

In western Minnesota and in eastern North Dakota farmers plowed as much corn land in the fall as time would permit. In other areas spring plowing, chiefly in April and early May, was the rule.

Small Grains and Flax Grown After Row Crops

The production of small grains or flax after an intertilled crop involves less preparation of the land because the seedbed has been partially prepared through the cultivation of the intertilled crop. The common operationsemployed in preparation of the seedbed and seeding small grains and flax when grown after row crops are shown in table 6.

As corn was the principal intertilled crop on surveyed farms, small grains and flax after row crops occurred almost exclusively in areas where corn was grown.

Plowing as a tillage operation in preparing land for small grains after row crops was not practiced to any great extent. It was most common in western Minnesota and in eastern North Dakota and eastern South Dakota. Where plowing was done, a common way was to plow, spike-tooth harrow 1 or 2 times and drill. In some areas the disk harrow, spring-tooth harrow or duckfoot cultivator was used on land that had been plowed.

The disk harrow was a common implement in practically all areas in preparing a seedbed for small grains where grown after row crops. In certain areas, particularly the central Dakotas and in northwestern Nebraska, it was a common practice to disk harrow 1 or 2 times and drill. In other areas disking 1 or 2 times, spike-tooth harrowing 1 or 2 times and drilling was a usual method.

In some areas the land was drilled without any other preparation. This was particularly true where winter wheat followed a row crop.

Small Grains and Flax where Alternated with Summer Fallow

Wheat alternated with summer fallow was largely confined to Montana and certain areas of North Dakota and western Minnesota. The usual operations in preparing the seedbed for spring and winter wheat where alternated with summer fallow are shown in table 7.

1/ Tillage and planting implements are abbreviated as follows: MP = moldboard plow, 1-way = vertical disk plow, DP = disk plow, H = spike-tooth harrow, Spt = spring-tooth harrow, D = disk harrow, P = packer, L = level, Duft = duckfoot cultivator, W = weeder, Dr = drill, End-gate = end-gate seeder.

The initial operation in working the summer fallow was mainly with the moldboard plow except in west-central Montana where the one-way vertical disk plow and the ordinary disk plow were substituted for the moldboard to a considerable extent.

Plowing was done mainly in June and July. The tillage operations that followed varied markedly, but the use of the duckfoot cultivator, spring-tooth harrow, and weeder to check weed growth and conserve moisture but leave the surface soil in a roughened condition to prevent soil blowing as much as possible, was much more in evidence than where wheat was seeded on non-summer-fallowed land.

Barley, oats and flax were not alternated with summer fallow to any appreciable extent but where they occupy this place in the cropping system the operations performed in working the summer fallow were quite similar to those for wheat.

Usual Planting Dates for Small Grains, Flax and Corn

The planting of small grains, flax, and corn may continue over a rather extended period depending on weather conditions and the acreage to be planted. The planting dates, as shown in figure 13, represent the usual period as reported by a majority of the farmers interviewed, but do not take into consideration variations due to differences in seasons.

Planting periods, as between areas, depend to a large extent on latitude and altitude. For example, the planting of spring wheat becomes general in southern South Dakota about March 25th and in northern North Dakota about April 15th,or 20 days later. Likewise the usual planting period for spring wheat in central North Dakota is about 10 days earlier than in an area of central Montana of about the same latitude but at a considerably higher elevation.

Production of small grains, flax and corn is to a certain degree competitive in the demands for labor and equipment. Planting of oats follows spring wheat, barley follows oats, flax follows barley, and corn follows flax. The seeding periods of spring wheat, oats, and barley are so nearly the same that an increase in one, without an increase in the labor supply, necessitates a decrease in the others.

In most cases, however, this is not a serious situation since large acreages of wheat relative to that of oats and barley are usually grown.

Common Sizes of Tillage and Planting Implements, Motive Power Units and Estimates of Rates of Work in Preparation of Seedbed and Planting Field Crops

The level to gently rolling topography which prevails on grain farms in most areas of the Northern Great Plains, together with farms of relatively large size, particularly adapts the employment of tractor power on field implements to this region. From the standpoint of least time required to perform different field operations, the implements in use should be those which, under particular soil and topographic conditions, fit the available power unit, whether it be animal power or tractor power. A fairly rapid change

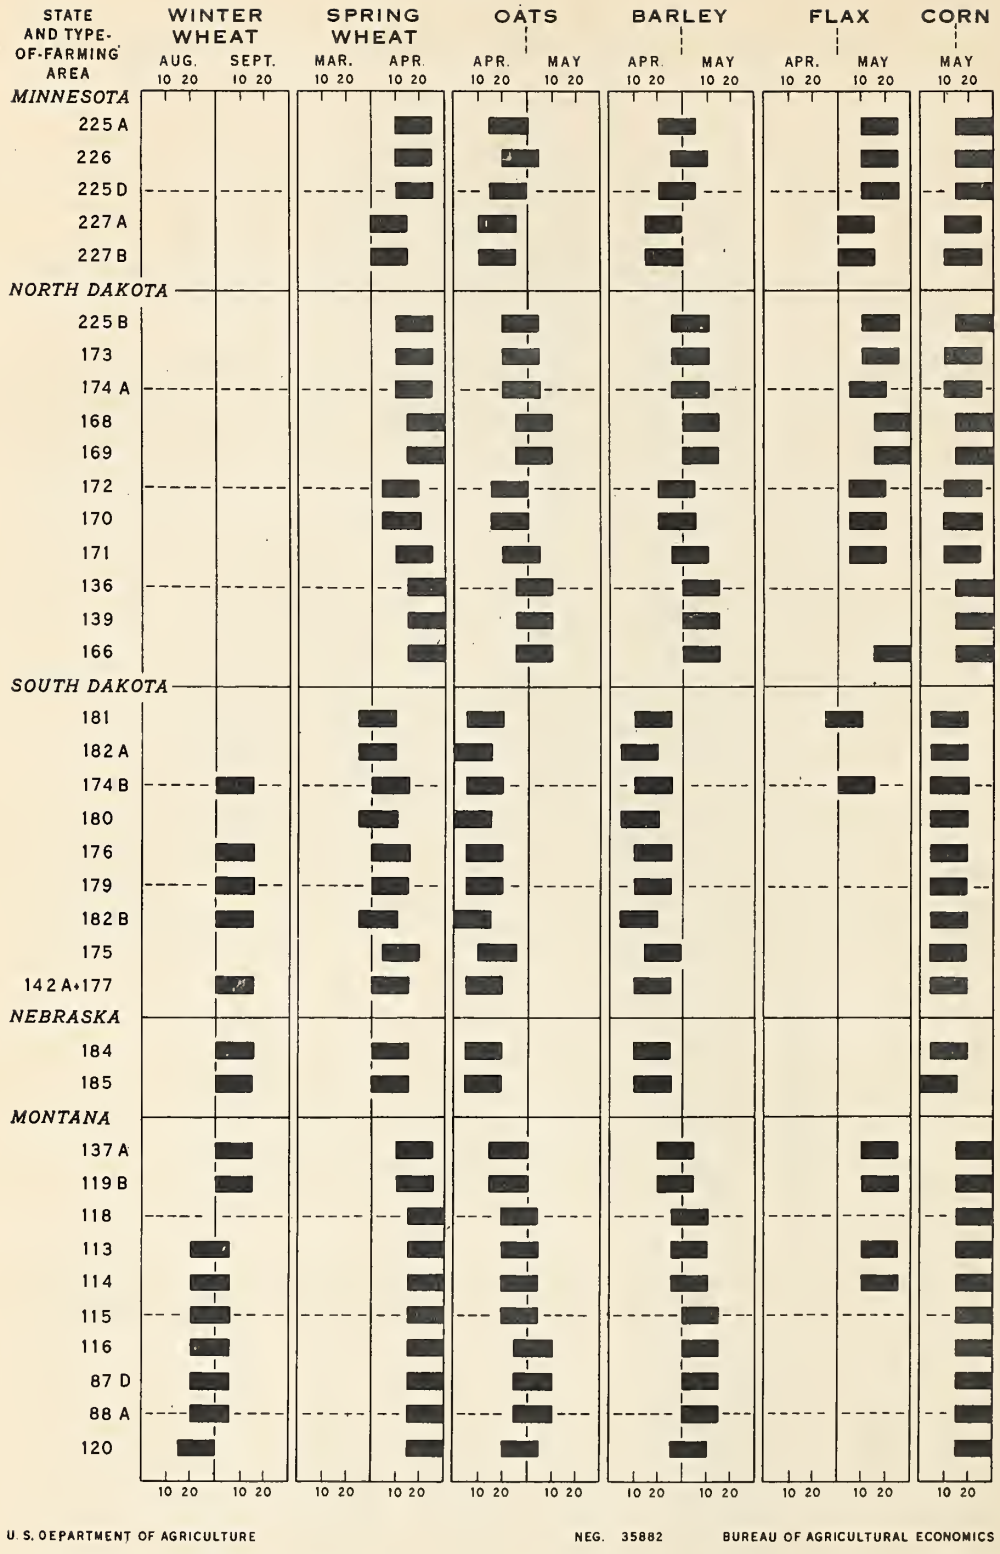

Figure 13. - Normal periods for planting small grains, flax, and corn by type-of-farming areas, Northern Great Plains

from horses to tractors has been taking place, and in some instances, horse-type equipment of improper size and type has been used with tractor power. Operators of such equipment cannot hope to equal the performance of other farmers who have implements properly related to their power units.

As previously stated the introduction of tractors mounted on rubber tires has been unusually rapid in the more easterly areas of the region. Where operating conditions are favorable, evidence points to an increase in accomplishment for certain tillage operations where tractors mounted on rubber are used. Tractor tests made by the Ohio Agricultural Experiment Station indicate that a tractor equipped with low pressure pneumatic tires has a lower rolling resistance than one having steel wheels and lugs, with the result that for certain operations a higher speed may be attained with the rubber-tired tractor or lower fuel consumption with the same implement at the same speed. 4/

Rubber tires also enable the operator to ride the tractor with greater comfort, make it possible to move equipment on hard surface roads and to operate in fields a considerable distance apart.

The Nebraska Agricultural Experiment Station reports on rubber-tired tractors as follows: 5/ " A saving in time and fuel can be made on most farm operations by using a tractor equipped with pneumatic tires. This saving becomes less significant and may become negative as drawbar pulls increase, necessitating low gear. This saving increases for those operations which make a relatively light load and permit the use of higher gears. Necessarily the tractors best adapted to rubber tires are those having sufficient speeds to utilize this advantage."

In response to an inquiry in June 1939 by the Bureau of Agricultural Economics, farmers in eastern South Dakota and in eastern North Dakota stated that most field operations that involve a relatively light load are performed in a shorter time when the rubber-tired tractor instead of the steel-wheel tractor supplied the motive power, but that planting operations and the first and second cultivation of corn were usually an exception to this rule. Some farmers stated that the use of the rubber-tired tractor did not result in a greater work accomplishment, but for the lighter loads a considerable saving in fuel was made.

The tillage and planting implements of the most common size and the motive power used to draw them are shown in tables 8 and 9. The accomplishments of these implements when drawn with horses and with tractors are shown in table 10. Although the use of certain implements drawn by tractors mounted on pneumatic tires undoubtedly has resulted in some increase in accomplishment, it is believed that the rates of work as shown for these implements are sufficiently accurate for general use.

1/ The size of implement is the working width and in some cases represents two or more implements in a combination hitch. In all cases where tractors are indicated as the source of power those of the high-wheel type were used.
2/ Drawbar horsepower tractor.

Table 9. - Common sizes of planting implements and motive power used in planting small grains, flax and corn by type-of-farming areas, Northern Great Plains 1/

	2-row lister cultivator	4 horses	12 to 15
	3-row lister cultivator	15 d.b.h.p. tractor	30 to 35
Planting corn	1-row lister planter	4 horses	7 to 9
	2-row lister planter	6 horses	14 to 16
	do	10d.b.h.p. tractor	18 to 20
	do	15 d.b.h.p. tractor	20 to 22
	1-row surface planter	2 horses	6 to 8
	2-row surface planter	do	12 to 15
	4-row surface planter	10 d.b.h.p. tractor	30 to 35
Drilling grain	8- or 9-foot grain drill	4 horses	15 to 18
	10-foot grain drill	4 or 6 horses	18 to 20
	do	10 d.b.h.p. tractor	30 to 32
	do	15 or 18 d.b.h.p. tractor	31 to 33
	11-foot grain drill	4 horses	20 to 22
	do	10 d.b.h.p. tractor	32 to 34
	12-foot grain drill	4 horses	22 to 24
	do	6 horses	24 to 26
	do	15 d.b.h.p. tractor	35 to 40
	14-foot grain drill	12 or 15 d.b.h.p. tractor	40 to 45
	20-foot grain drill	15 d.b.h.p. tractor	50 to 55

1/ The size of implement is the working width and in some cases represents 2 or more implements in a combination hitch.
2/ In all cases where tractors are indicated as the source of power those of the high-wheel type were used.
3/ Drawbar horsepower tractor.

There are, of course, other combinations of implements and power that differ in size from those shown in these tables, but only those that were in sufficient numbers to give a fairly reliable figure on accomplishment are shown. In certain areas, 2 or more implements were used in a combination hitch, but no attempt has been made to show the accomplishments of implements used in this way.

Plows of the moldboard type were the ones most commonly used except in north-central Montana, where ordinary disk plows and one-way vertical disk plows were used more extensively than those of the moldboard type. Plowing with horses was confined mainly to 2-bottom or smaller moldboard plows. Larger plows were drawn for the most part with tractors. A 5-horse team was the most common source of power used with 2-bottom moldboard plows and the addition of another horse to make a 6-horse team did not result in a greater work accomplishment per day. Likewise, an increase in motive power over that supplied by a 15-drawbar horsepower tractor on a 3-bottom 14-inch moldboard plow did not result in covering a greater number of acres per 10-hour day. The use of a 15-horsepower instead of a larger tractor to draw a 3-bottom 14-inch moldboard plow also resulted in a considerable saving in fuel. But the use of a 20-horsepower instead of a 15-horsepower tractor with a 4-bottom 14-inch moldboard plow resulted in an increase of about 20 percent in acres plowed per 10-hour day. Vertical disk plows were all drawn with tractors and covered about 3 acres of ground per foot of width.

Spike-tooth harrows were mainly those of from 15- to 28-foot width drawn with from 4- to 6-horse teams. The most common size was the 20-foot harrow drawn with a 4-horse team. For 20-foot spike-tooth harrows the use of a 6-horse team instead of 4 horses resulted in an increased accomplishment of only 5 percent. For spike-tooth harrows of 24-foot width or larger, an increase in size of team resulted in an appreciable increase in acres covered per 10-hour day.

Tractors of 10- and 15-drawbar horsepower were most commonly used as the source of motive power for tractor-drawn spike-tooth harrows. The use of the larger tractor on a given size of implement did not result in greater accomplishment per day. Spike-tooth harrows drawn with horses covered approximately 2 acres per 10-hour day per foot of width whereas spike-tooth harrows drawn with tractors accomplished approximately 3 acres per 10-hour day per foot of width.

Spring-tooth harrows were of minor importance. They were mainly of 10-and 12-foot widths drawn with 4- and 6-horse teams and 15-drawbar horsepower tractors.

Cultivation with the duckfoot cultivator was mainly with those of from 7- to 12-foot width, those of over 8-foot width were drawn mainly with tractors. Horse-drawn duckfoot cultivators covered approximately 2 acres per 10-hour day for each foot of width, whereas tractor-drawn implements covered about 3 acres per 10-hour day for each foot of width.

Single disk harrows were drawn almost entirely with horses, whereas tandem disk harrows were chiefly drawn with tractors. The acreage covered per 10-hour day with each type of disk of a given size where drawn with the same power unit was practically the same. A material saving of time resulted from the use of the tandem disk where it was necessary to disk the land more than once.

Small packers were used behind moldboard plows in certain areas, particularly in North Dakota. Packers not used in connection with moldboard plows were mainly those of from 9- to 12-foot width. They were drawn almost exclusively with 4 horses. An increase in width of packer resulted in an increased accomplishment per day but not always in proportion.

In central and western South Dakota and in northwestern Nebraska, corn was cultivated with the lister as well as with surface cultivators. In other areas corn cultivation was almost exclusively with the surface cultivator. The work was done with 1-, 2-, 3-, and 4-row cultivators, but 1-row cultivators drawn with 2 horses and 2-row cultivators drawn with 4 horses were by far the most common. Two-row shovel cultivators drawn with 4 horses covered approximately twice as much acreage per 10-hour day as did 1-row cultivators drawn with 2 horses.

Planting corn was with 1- and 2-row lister planters and with 1-, 2-, and 4-row surface planters. By far the greatest amount of this work was with a 2-row surface planter drawn with 2 horses, except in central and western South Dakota and in northwestern Nebraska, where corn planting with a lister planter was a common practice. The 2-row lister planter drawn with a 15-drawbar horsepower tractor accomplished about 45 percent more work in a 10-hour day than when drawn with 6 horses.

Grain drills in use were mainly those of from 8- to 20-foot width. The majority were 10-foot disk drills drawn with 4 horses. Press drills were used to a limited extent, principally in North Dakota, and deep-furrow drills were not found in appreciable numbers except in Area 115 of Montana. An increase in tractor power over the 10-horsepower tractor in connection with a 10-foot drill did not result in an appreciable increase in accomplishment per day. Horses were not used with drills of more than 12-foot width. The use of a 20-foot instead of a 12-foot drill drawn with a 15-horsepower tractor resulted in an increase in accomplishment per day of about 40 percent.

The labor and power used per 100 acres in preparing seedbed and planting small grains, flax and corn according to their place in the cropping system are given by type-of-farming areas in appendix tables 29 to 43. A summary of these labor and power requirements is shown in appendix table 44.

HARVESTING SMALL GRAINS AND FLAX

Wheat, oats, barley, and flax were harvested for grain in three different ways, namely, with the combined harvester-thresher which completes the work in one operation; with the binder and threshed from the shock with a stationary separator; and with the header and threshed from header-stacks with a stationary separator.

Proportion of Small Grain and Flax Acreage Harvested in Different Ways

Wheat was mainly harvested with the combined harvester-thresher on surveyed farms in most areas of Montana, northwestern Nebraska, and western North Dakota and South Dakota.

In western Minnesota and in eastern North Dakota and South Dakota, 77 percent or more of the wheat acreage was cut with the binder and the remainder largely harvested with the combine. In south-central and southwestern North Dakota 53 percent or more of the wheat acreage was harvested with the header (fig. 14). In many areas where grain harvest is usually with the combine it is not an uncommon practice for farmers to have an additional investment in a binder or header which may be used when the small grain crop is short and they desire to save more straw and chaff. When the acreage to be harvested is fairly large it is generally recognized that harvesting with the combine involves a lower cost than with the binder or header. Since the method of harvesting has its influence on costs and as it is not uniform from year to year perhaps harvesting costs in these drought areas should be averaged over a period of years rather than shown annually. Harvesting with binder or header savesstraw and reduces the feed bill the following year. An average for the region indicated that 50 percent of the wheat acreage was harvested with the combine, 36 percent with the binder and 14 percent with the header.

Oat harvest on surveyed farms in most areas was for the most part with the binder. In south-central and southwestern North Dakota, from 30 to about 80 percent of the oats acreage was cut with the header and the remainder largely cut with the binder. In other areas two-thirds or more of the acreage was cut with the binder. For the entire region about 92 percent of the acreage was cut with the binder, 4 percent with the header and 4 percent with the combine (fig. 15). The greater use of the binder to harvest oats is because many farmers desire to save the oats straw for feed.

Barley harvest in western Minnesota, North Dakota and in eastern South Dakota, from the standpoint of acreage harvested with the binder, header and combine followed about the same general pattern as for wheat (fig. 16). For most areas of western South Dakota, northwestern Nebraska, and Montana the acreage of barley cut with the binder was materially larger than that of wheat. For the entire region approximately 70 percent of the barley acreage was cut with the binder, 11 percent with the header and 19 percent with the combine.

Flax on surveyed farms in western Minnesota was practically all harvested with the binder. In south-central North Dakota harvest of flax with the header was the common method. In other areas of North Dakota 55 percent or more of the flax acreage was cut with the binder and the remainder harvested with the combine. In eastern South Dakota harvest of flax with the binder was by far the most common method. In other areas of South Dakota, Nebraska, and Montana flax was grown to only a limited extent. In these areas

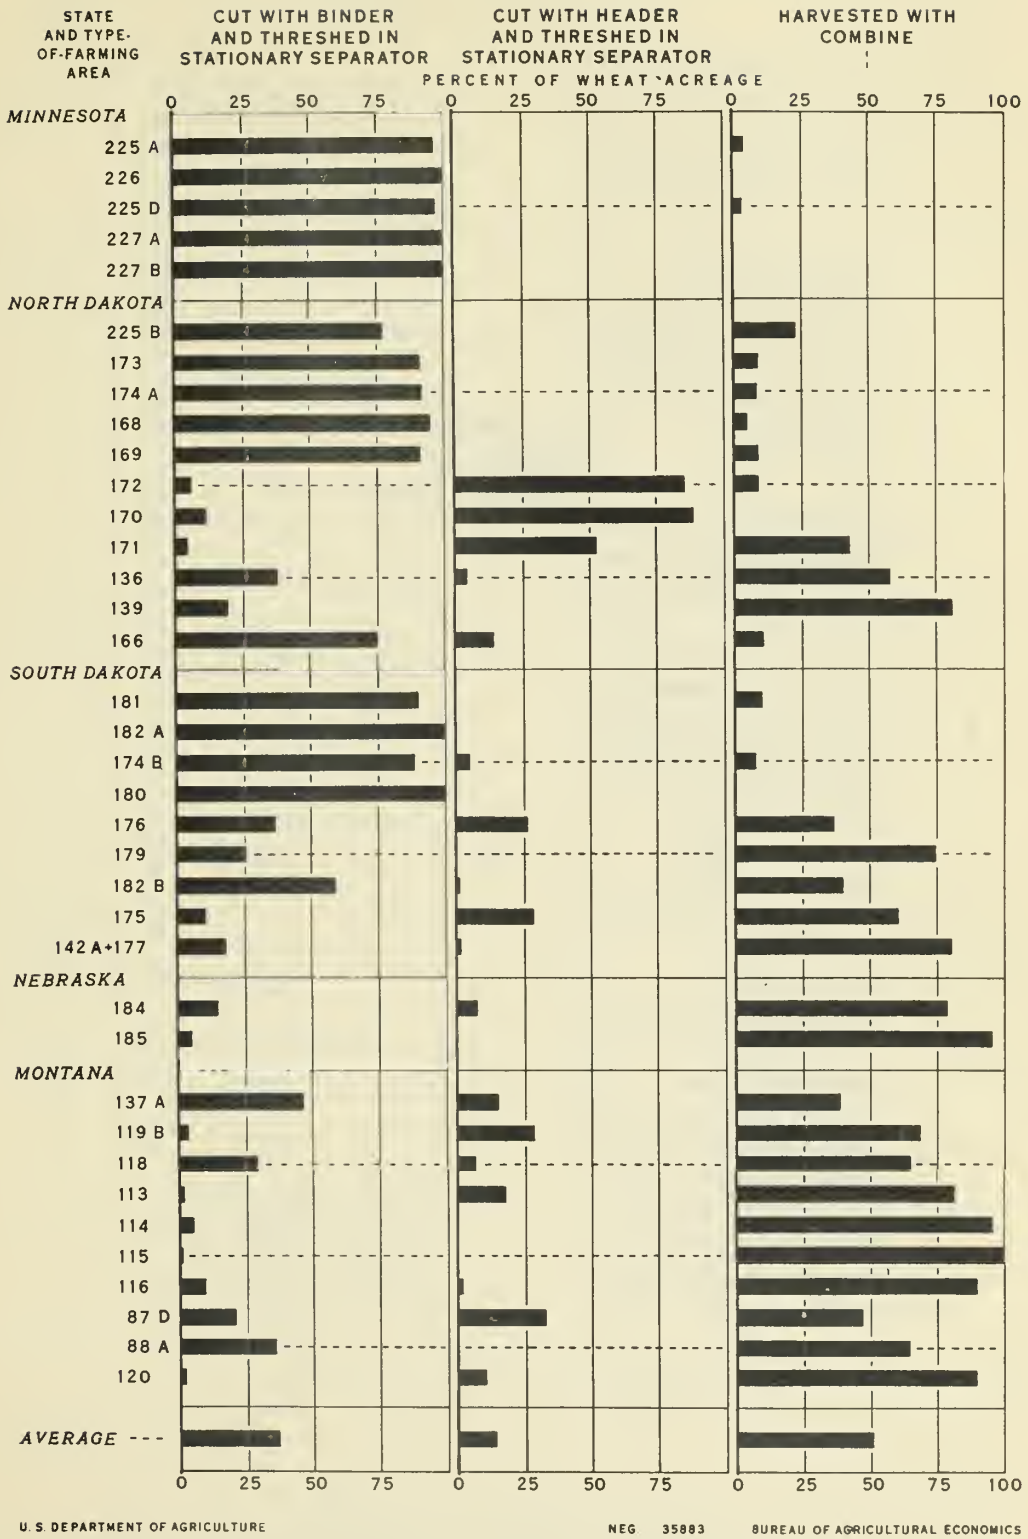

Figure 14. - Proportion of wheat acreage harvested by different methods on surveyed farms by type-of-farming areas, Northern Great Plains, 1933

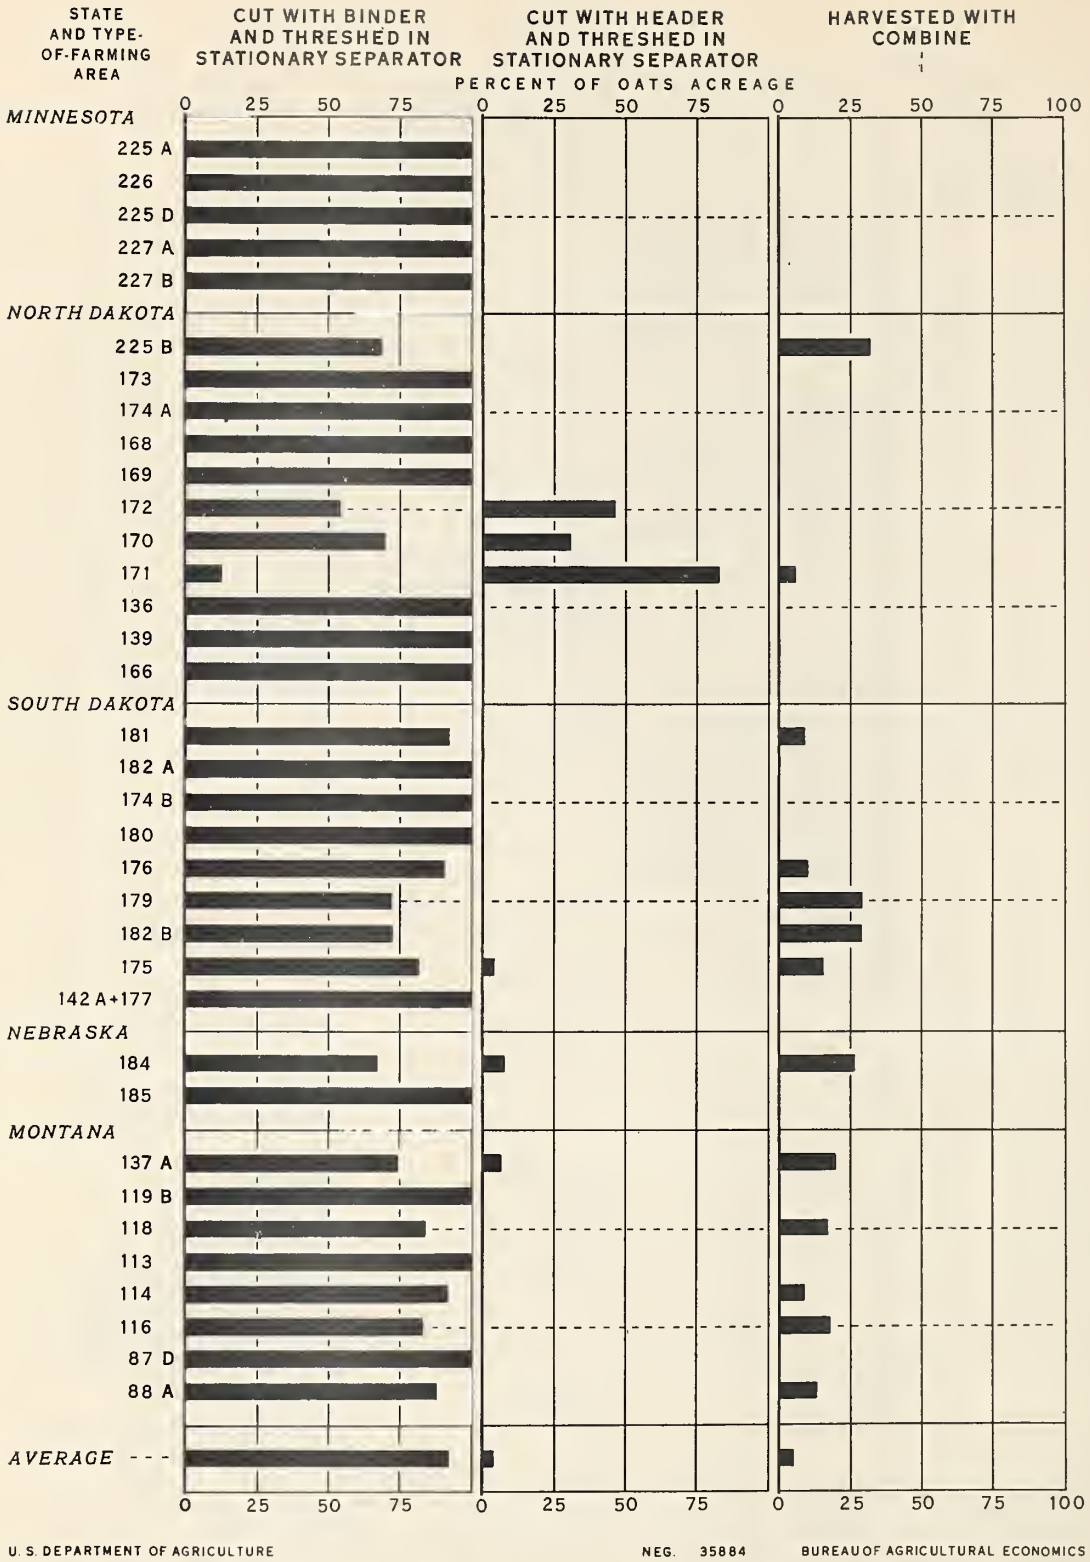

Figure 15. - Proportion of oats acreage harvested by different methods on surveyed farms by type-of-farming areas, 1933

Figure 16. - Proportion of barley acreage harvested by different methods on surveyed farms by type-of-farming areas, Northern Great Plains, 1933

where flax occurred, the combine method of harvesting was the most common. For the entire region about two-thirds of the flax acreage was cut with the binder, 25 percent with the combine and 8 percent with the header.

Harvesting with the Combined Harvester-Thresher

A survey of harvest labor in North Dakota in 1938 ihdicates that the small combine (5- and 6-foot cutter-bar widths) is being used to a considerable extent in certain areas of eastern North Dakota. 6/

Of 201 Cass County farms surveyed in area 174A, 10 percent had combines of 5- or 6-foot cutter-bar widths. Of 227 Walsh County farms surveyed in area 225A, 7 percent had combines of 5- or 6-foot cutter-bar widths. In both areas other combines were mainly of 10- and 12-foot cutter-bar widths. According to this survey, combines of less than 6-foot cutter-bar widths were not used to any appreciable extent in other areas of North Dakota in 1938..

These small combines harvested an average of 119 acres of small grains and flax per combine of which 67 percent was represented by wheat; 5 percent by oats; 20 percent by barley; 5 percent by rye and 3 percent by flax. They were all mounted on pneumatic tires and drawn with tractor power. With the 5-foot combine a crew of 2 men, 1 man to operate the combine and the tractor and 1 man to haul the grain away in a truck, harvested and stored small grain at the rate of 15 to 17 acres per 10-hour day.

Harvesting wheat with the combine has become an established practice in the more westerly areas of the Northern Great Plains (table 11). In the western Dakotas and in the areas surveyed in northwestern Nebraska and in Montana, with the exception of areas 87D and 137A in Montana, from 23 to 85 percent of the farmers interviewed had combines. For the region as a whole, 22 percent of the farm operators interviewed had one or more combines.

In order to warrant the purchase of the larger combine a rather substantial acreage of grain is needed. The crop acreage per farm for surveyed farms that had combines averaged approximately 746 acres per farm compared with 339 acres per farm for farms without combines, or the average crop acreage per farm was 120 percent larger for farms with than for farms without combines. In combine areas on farms so small that the owners did not consider that they had sufficient acreage to warrant the purchase of a combine, it was a common practice to hire the grain harvested with a combine on a contract basis.

6/ Cooperative survey made by the Farm Security Administration, Bureau of Agricultural Economics and the North Dakota Agricultural Experiment Station. Unpublished data in files of the Agricultural Experiment Station.

Common Sizes of Combines, Motive Power Units, Labor Crews and Rates of Harvest Work

The most common size of combines and motive power used to draw them are shown by type-of-farming areas in table 12. Combines varied in size from 8- to 24-foot cutter-bar widths, with a tendency for the larger sizes to appear most frequently in those areas having the largest wheat acreage per farm. The 12-foot cutter-bar combine was the most common size, and was followed in order by those of 16-and 15-foot cutter-bar widths. All combines included in the survey except one were drawn with tractors. The high-wheel 15-drawbar horsepower tractor was the most common size used to draw combines of all sizes except the 24-foot combine. Twenty-four foot combines were drawn with 50-horsepower track-laying tractors.

The grain was all bulked. An operating crew of two men, one man on the tractor and one man on the combine was usual for most combines. Of the combines represented in the survey, 92 percent were operated with a 2-man crew, 3 percent, mainly of the smaller sizes, were operated with a 1-man crew, and 5 percent, mainly of the larger sizes, were operated with a 3-man crew. The rates of work with combines of different sizes when drawn with designated power units are given in table 13. The acreage of grain cut per 10-hour day was about $2\frac{1}{2}$ times the cutter-bar width.

Table 13. - Estimates of rates of work in harvesting small grains with combines of different sizes, Northern Great Plains

Size of combine (Length of cutter-bar)	Power unit (drawbar horsepower rating)	Usual acreage per 10-hour day
		Acres
10-foot combine	15 h.p. high-wheel tractor	20 to 25
12-foot combine	15 or 18 h.p. high-wheel tractor	25 to 30
15-foot combine	15 h.p. high-wheel tractor	30 to 35
16-foot combine	15 or 18 h.p. high-wheel tractor	32 to 37
20-foot combine	15 or 18 h.p. high-wheel tractor	40 to 45
24-foot combine	50 h.p. track-type tractor	50 to 55

The labor used in hauling grain from the combine depends upon the threshing rate, the distance hauled and whether the work is done with horses or motor trucks. Delivery of grain to the elevator with motor trucks was the common method in most areas. Combines are equipped with grain tanks and the grain is delivered direct from the grain tank into the motor truck. With normal yields, 1 man with a motor truck of 100-bushel capacity can haul the grain that would be harvested with a 16-foot combine, providing the distance does not exceed 5 or 6 miles. The capacity of the motor truck usually exceeds that of the grain tank. To insure against delay in emptying the grain tank an extra man with team and wagon is sometimes used to store the grain until the motor truck returns from the elevator. Where this is the case 1 motor truck can deliver the grain a distance of 10 or 12 miles. For longer hauls 2 or more motor trucks are usually required.

1/Drawbar horsepower high-wheel tractor. 2/Drawbar horsepower track-laying tractor.

The labor and power used per 100 acres in harvesting and hauling small grains and flax where harvested with the combine are shown by type-of-farming areas in appendix tables 45 to 48.

Acreage of Grain Cut Annually by Combines

The distribution of combines by total acres cut annually and by size of machine is shown in table 14. Sixty-eight percent of the 12-foot combines cut 400 or fewer acres annually, whereas 61 percent of the 16-foot combines cut over 400 acres annually. For combines of all sizes 37 percent cut 300 or fewer acres; 46 percent cut from 301 to 700 acres and 17 percent cut over 700 acres annually.

Harvesting with Binder and Header and Threshing with the Stationary Separator

Harvesting of wheat, oats, barley, and flax with binders and headers and threshing in stationary separators was practically all done in 2 different ways, namely, harvesting with the binder and threshing bundle grain from shock, and harvesting with header and threshing headed grain from stack.

Common sizes of grain binders and headers and motive power are shown in table 15. Seven- and 8-foot binders were most common and were for the most part drawn with 4-horse teams. Headers were largely of 12-foot cutter-bar widths and were mainly propelled with 4- and 6-horse teams.

1/ Drawbar horsepower high-wheel tractors.

Rates of work for the operations in harvesting small grains and flax with the binder and header are shown in table 16. All of these operations are influenced to some extent by the yield of grain and straw. The acreage of grain harvested per day with the binder increased about in proportion to the increase in size of binder used. The use of tractor power instead of horsepower increased the rate of work by about 35 percent.

Table 16. - Operations, kind and size of implements, size of crew, motive power and rates of work in harvesting wheat, oats, barley and flax for grain, Northern Great Plains

Operation	Kind and size of implement	Crew (men)	Power unit		Usual acreage per 10-hour day
			Horses	Tractor (drawbar rating)	
		Number	Number	Size	Acres
Cutting	6-foot binder	1	4	-	10 to 12
do	7-foot binder	1	4	-	14 to 16
do	8-foot binder	1	4	-	15 to 18
do	do	2	-	10 or 15 horse-power	20 to 25
do	10-foot binder	2	-	10 or 15 horse-power	25 to 30
Shock					
Wheat		1	-	-	16 to 18
Barley		1	-	-	15 to 17
Oats		1	-	-	14 to 16
Flax		1	-	-	15 to 17
Cutting and stacking headed grain	12-foot header and 2 barges	5 1/	8 1/	-	20 to 25
do	do	5 2/	10 2/	-	25 to 30
do	do	6 3/	4 3/	10 horsepower	28 to 32

1/ Includes 1 man and 4-horse team on header and 4 men and 2 2-horse teams to haul and stack.
2/ Includes 1 man and 6-horse team on header and 4 men and 2 2-horse teams to haul and stack.
3/ Includes 2 men to operate header and 4 men and 2 2-horse teams to haul and stack.

Where a 4-horse team was used to propel the header, a number of farmers used one header barge with a crew of 2 men and a 2-horse team to stack the headed grain. One barge was used only when yields were light. The acreage cut and stacked per day was about 20 percent less than when 2 barges were used. Practically all farmers that used a 6-horse team or tractor motive power to propel the header, hauled and stacked the headed grain with 2 barges with a 2-horse team for each barge, and a crew of 4 men. The common size of separators and threshing outfits where headed grain was threshed from the stack and where bundle grain was threshed from the shock is shown by type-of-farming areas in tables 17 and 18. Separators were largely of 22-inch and 28-inch cylinder capacity.

Table 17. - Common size of separators and labor crews where headed grain was threshed from stack, by type-of-farming areas, Northern Great Plains

A typical crew with a 22-inch cylinder separator where headed grain was threshed from the stack consisted of 4 or 5 men while the 28-inch cylinder separator was operated with 4, 5, or 6 men. Where bundle grain was threshed from the shock, a typical crew with the small separator consisted of 4 men with teams to haul in the bundles and 1 or 2 men at the machine. The 28-inch and 32-inch cylinder separators were typically operated with crews of 8 or 10 men with 6 or 8 men with teams hauling bundle grain and 2 men at the machine. The rates of work where headed grain was threshed from the stack are given in table 19 and where bundle grain was threshed from the shock in table 20.

Table 19. - Estimates of rates of work in threshing headed grain from stack with separators of designated sizes and designated labor crews, Northern Great Plains.

Crop	Yield per acre	Separator (size of cylinder)	Crew (men)	Threshing rate per 10-hour day
	Bushels	Inches	Number	Bushels
Wheat	4.9	22	5	446
Wheat	5.4	28	4	550
Wheat	6.1	28	5	690
Wheat	5.6	28	6	624
Barley	7.3	28	4	530
Barley	14.9	28	5	950
Barley	6.6	28	6	705

Grain, threshed in a stationary separator, was delivered direct from the separator, either into a wagon box or motor truck. Where wheat was hauled direct to the elevator the motor truck was commonly used and the rate of delivery was somewhat faster than when hauled direct from the combine to the elevator. Because of higher yields and a more bulky product the labor requirement for delivery of barley and oats was somewhat higher than that of wheat. Two wagons were commonly used for farm storage of grain with 1 man and 2-horse team for each wagon.

The labor and power used per 100 acres in harvesting, threshing and hauling wheat, oats, barley, and flax where cut with binder and header and threshed in the stationary separator are shown by type-of-farming areas in appendix tables 49 to 56. A summary of these labor and power requirements is given in appendix table 57.

HARVESTING CORN

Corn was harvested in a number of different ways. The several methods included husking from standing stalks; cutting with the corn binder; harvesting with the corn picker; cutting with the grain binder; cutting with the corn sled; cutting by hand and harvesting with livestock. Husking from standing stalks and cutting with the corn binder were by far the most common methods.

In southwestern Minnesota, from 50 to 70 percent of the corn acreage was husked from standing stalks and the remainder largely cut with the corn binder. In other areas of western Minnesota, 80 percent or more of the corn acreage was cut with the corn binder.

In North Dakota, with the exception of areas 168, 169, 136, and 166, 65 percent or more of the corn acreage was cut with the corn binder and the remainder largely husked from standing stalks. In areas 168 and 169, about one-half of the corn acreage was husked from standing stalks and about one-half cut with the corn binder. In areas 136 and 166, 55 percent or more of the corn acreage was cut with the grain binder and the remainder largely cut with the corn binder.

In areas 181, 174B and 175 of South Dakota, about one-half of the corn acreage was cut with the corn binder and the remainder largely husked from standing stalks. In other areas of the State, husking from standing stalks was the most common method.

In northwestern Nebraska, practically all of the corn harvest was from standing stalks.

In eastern Montana, harvest of corn with the corn binder was the most common method. The limited acreage grown in other areas of the State was cut with the grain binder, cut with the corn sled, or harvested with livestock.

In eastern South Dakota and southwestern Minnesota, from 10 to 30 percent of the corn acreage was harvested with the corn picker.

Corn husked from standing stalks was usually with an outfit consisting of 1-man, 2-horse team and wagon. For a yield of 20 bushels per acre, this outfit husked and stored corn at the rate of 50 bushels per 10-hour day.

Corn cut with the corn binder was either fed unhusked or put in the silo. Corn binders were all 1-row machines and usually operated with 1 man and a 3-horse team. The usual acreage cut per 10-hour day was 6 to 8 acres. The bundle corn was shocked at the rate of 5 or 6 acres per 10-hour day. Stacking of bundle corn with the usual outfit consisting of 2 men and wagon drawn with a 2-horse team was at the rate of 7 or 8 tons per 10-hour day.

Very little of the corn on surveyed farms was ensiled except in northeastern South Dakota and southwestern Minnesota. The rates of work in filling silos are not given, since reports of silo filling on surveyed farms were not in sufficient numbers to determine typical labor crews, power units and size of ensilage cutters.

Corn pickers were all 1-row machines. The usual crew consisted of 2 men, 1 to operate the tractor and picker and 1 man and team to haul and crib the corn. With this outfit 8 to 10 acres of corn were harvested and stored per 10-hour day. Where wagon hitches were not used, or if the distance to the crib was unusually long, an extra man and team were used in hauling and cribbing the corn.

NORMAL HARVEST PERIODS FOR SMALL GRAINS, FLAX AND CORN

The harvesting dates as shown in figure 17 represent the period when harvest is general and do not take into consideration variations in dates due to variations in seasons. Harvest with the combine and header was about 5 to 10 days later than when the binder was used. Spring wheat harvest was about 5 to 20 days later than winter wheat harvest. Spring wheat harvest with the combine in southern South Dakota was 10 to 15 days earlier than in northern North Dakota for areas of about the same longitude.

Figure 17. - Normal period for harvesting small grains, flax, and corn by type-of-farming areas, Northern Great Plains

MAKING HAY

Prairie hay, small grains, chiefly oats and barley cut for hay, and alfalfa make up the principal hay crops on surveyed farms in the Northern Great Plains. Prairie hay was not produced on surveyed farms in Montana except in the eastern and northwestern parts of the State and in these areas to only a limited extent. It was produced in practically all other areas; its greatest production being in central North Dakota and South Dakota. The greatest use of small grains for hay was in Montana, western North Dakota, northwestern Nebraska and southwestern Minnesota. Alfalfa was produced in greatest abundance in west-central Montana, northwestern Nebraska, eastern North Dakota, eastern South Dakota, and in northwestern Minnesota. For the region as a whole about 50 percent of the hay acreage was represented by prairie hay, 25 percent by grain hay, and 17 percent by alfalfa hay (table 21).

Common Sizes of Hay Harvesting Implements, Motive Power Units and Rates of Work

The common kinds and sizes of hay harvesting implements and the motive power used to draw them are shown in table 22. Seven- and 8-foot binders drawn with 4 horses, 12-foot headers drawn with 4 horses or a 15-drawbar horsepower high-wheel tractor, 5- and 6-foot mowers drawn with 2 horses and 10- and 12-foot sulky and sweep rakes drawn with 2 horses were the most common hay harvest implements.

The mowing machine was used to cut all prairie hay and alfalfa and most of the grain hay and sweet clover. From 3 to 7 percent of the sweet clover acreage was cut with the binder in eastern North Dakota. In other areas of the region it was all cut with the mower. Where sweet clover was cut with the binder it was a common practice to tie in loose bundles and cure in long shocks.

In northwestern North Dakota and northern Montana, from 15 to 45 percent of the grain hay was cut with the binder and in area 113 of Montana about 25 percent was cut with the header. In other areas practically all grain hay was cut with the mower. The rates of work in cutting and raking hay are shown in table 23.

Storage of Hay

Farmers in most areas put as much alfalfa hay in the barn as space would permit, the remainder being stacked. Because of the tendency of sweet clover to heat when put in the barn, it was usually stacked. Prairie hay and grain hay were usually stacked.

Hay stored in barns was hauled in wagons drawn with 2-horse teams. A number of different crews were used. With 1 wagon and a 2-horse team, crews of 1, 2, or 3 men were used but a 2-man crew was the most common. Where 2 wagons and two 2-horse teams were used, the most common labor crew consisted of 3 or 4 men.

10-foot sulky rake	do	18 to 20
12-foot sulky rake	do	20 to 24

1/ Drawbar horsepower high-wheel tractor.

Hay stored in stacks was either hauled to the stack in wagons or conveyed to the stack with the sweep rake. Grain hay was practically all hauled to the stack in wagons and stacked by hand methods. On the other hand a number of different ways were used in stacking alfalfa and prairie hay. Sometimes it was hauled with wagons and elevated to the stack with an overshot stacker, or it might be conveyed to the stack with a sweep rake and stacked by hand. However most of the alfalfa and prairie hay was either hauled to the stack in wagons and stacked by hand methods or conveyed to the stack with the sweep rake and elevated to the stack with the overshot stacker.

Where sweep rakes and overshot stackers were used, the usual crew consisted of 3 men, 1 man and a 2-horse team on the sweep rake, 1 man on the stack and 1 man and a stacker team to elevate the hay to the stack. An outfit of this size stacked alfalfa and sweet clover yielding about 1 ton per acre, at the rate of 12 to 14 tons per 10-hour day. Prairie hay yielding about .5 tons per acre was stacked with sweep rake and overshot stacker at the rate of about 10 to 12 tons per 10-hour day.

Where hay was hauled to the stack in wagons and stacked by hand methods, a wagon drawn with a 2-horse team and a crew of 2 men was the most common. Where 1 wagon was used, hay yielding from .5 to .75 tons per acre was hauled and stacked at the rate of 6 to 8 tons per 10-hour day.

The hours of labor and power used per 100 acres in making different kinds of hay are shown in appendix table 58.

APPLICATION OF BASIC DATA TO INDIVIDUAL FARMS

The data included in this report are not intended to serve as a basis for budgeting all of the productive resources of these cash grain farms. They should, however, serve a useful purpose in setting up standards for field work. Successful planning of a cropping system involves a knowledge of the proper kinds and sizes of farm implements and the time necessary to perform the desired operations on a given acreage. This principle is illustrated by the following example of standards for field work in preparing seedbed, planting, and harvesting spring wheat on a typical wheat farm (table 24). This illustration applies to area 137A of Montana and is based on spring wheat alternated with summer fallow and harvested with a combine. The method applies as well to spring wheat or other field crops grown after small grains or row crops and harvested by other methods.

Table 24. - Standards for field work in preparing seedbed, seeding, harvesting and marketing 100 acres of spring wheat where alternated with summer fallow

Kind and amount of work	Size of crew, power, and size and type of implement used	Rate of work per 10-hour day	Total				Usual period for field work
			Man labor	Horse work	Tractor work	Truck work	
			Hours	Hours	Hours	Hours	
Plowing (100 acres)	1-man and 15 d.b. h.p. tractor, 1/ 3-bottom 14-inch moldboard plow	12 acres	83.3	-	83.3	-	June 1 to July 1
Disking (100 acres)	1-man and 15 d.b. h.p. tractor, 10-foot tandem disk harrow	30 acres	33.3	-	33.3	-	July
Harrowing (200 acres)	1-man and 4-horses 20-foot spike-tooth harrow	38 acres	52.6	210.4	-	-	July and April
Drilling (100 acres)	1-man and 4-horses 10-foot disk drill	20 acres	50.0	200.0	-	-	April 10 to April 25

APPENDIX

Tables 25 to 58 included are intended for the use of those who require detailed information other than that given in the tables and charts that precede them.

Tables showing the labor and power in preparing seedbed and seeding field crops and in harvesting crops by different methods are based on the methods of production and harvesting which were discussed in some detail in the main body of the text. A wide range in methods employed on different farms as well as a considerable range in different areas are shown. The labor and power requirements are influenced by soil and topography, size and shape of fields, size and type of implements, and size and type of power units. The hours of labor and power for some crops, especially oats, barley and flax in certain areas, are represented by only a few observations. For this reason, differences in hours of labor and power used on certain crops as between these type-of-farming areas may not be significant. However, averages for the region probably represent closely the normal requirements.

In general, the hours of man labor for seedbed preparation and seeding were highest where the crop in question was alternated with summer fallow, somewhat lower where seeded after small grains, and lowest where seeded after a row crop. The hours of man labor for harvesting and threshing were highest where small grains were harvested with the binder, somewhat lower where harvest was with the header, and considerably lower where harvest was with the combine.
